You see in Fig. 9B that the full width half maximum of each emission spectrum is <35 meV, and there is practically no Stokes shift for the three thickest NPLs. The small width of the band edge NPL absorption line clearly shows that this width is not connected with fluctuations of the NPL thickness, as the NPLs are atomically flat. A Stokes shift of 70 meV is observed only for the thinnest CdSe NPLs, which is only two monolayers thick. This suggests that the uniformity of NPLs begins to drop in the 12-angstrom-thick structures.

Fig. 9 Transmission electron microscopy (TEM), absorption and photoluminescence of CdSe NPLs. A—TEM images of CdSe NPLs. B—Absorption spectra and photoluminescence measured in two-, three-, four-, and five-monolayer-thick nanoplatelets. Panel A: Reproduced with permission from Ithurria S, Dubertret B (2008) Quasi 2D colloidal CdSe platelets with thicknesses controlled at the atomic level. *Journal of the American Chemical Society* 130: 16504–16505 (Copyright 2008 AMERICAN Chemical Society). Panel B: Modified with permission from Ithurria S, Tessier MD, Mahler B, Lobo RPSM, Dubertret B, Efros AL (2011) Colloidal nanoplatelets with two-dimensional electronic structure. *Nature Materials* 10: 936–941 (Copyright 2011 Springer Nature).

How can we describe the absorption spectra of CdSe NPLs? The procedure used is similar to the one applied to the description of the optical properties of quantum wells, with a difference resulting from the small dielectric constant of the surrounding NPL dielectric constant matrix. First, one needs to calculate the optical transition energy between the lowest electron and hole quantum confined levels equal to

$$E_g + E_e^{2D}(1) + E_h^{2D}(1) = E_g + \frac{\hbar^2 \pi^2}{2m_e L^2} + \frac{\hbar^2 \pi^2}{2m_h L^2}, \quad (12)$$

where the energy of the electron and hole 2D subbands calculated in parabolic band approximation is described in Eq. (2). Eq. (2) does not consider, however, the self-interaction of electrons and holes with their own image, that shifts the quantum confined levels to higher energy (see Fig. 8B). These self-interaction energies for the lowest level of electrons, Σ_e , heavy holes, Σ_{hh} , and light holes, Σ_{lh} , can be calculated in first order perturbation theory, and they are equal to each other in the parabolic band approximation. The calculated dependence of these energies on NPL thickness is shown in Fig. 10A (Botao et al., 2020). The small difference of these energies that can be seen in the narrowest NPLs is connected with taking into account the nonparabolicity of the electron and hole energy spectra in CdSe. The self-interaction energy of Σ_{lh} , as you can see from this Fig. 10A, is larger than the others, because the light hole on average is closer to the NPL surface. As a result, for the total energy of the optical transition between the lowest electron and the heavyhole sublevels and between the electron and light-hole sublevels, the effective energy gaps can be written as:

$$E_{g,e-hh;e-lh}^{2D}(1) = E_g + \frac{\hbar^2 \pi^2}{2m_e L^2} + \frac{\hbar^2 \pi^2}{2m_{hh;lh} L^2} + \Sigma_e + \Sigma_{hh;lh}, \quad (13)$$

where m_{hh} and m_{lh} are the heavy hole and light hole effective masses, respectively. The calculated size dependence of the energy gap between non-interacting electrons and heavy holes is shown in Fig. 10B from Benchamekh et al. (2014). This energy gap could be measured in STM experiments as was shown by Botao et al. (2020).

As discussed above the electron-hole Coulomb interaction is significantly enhanced due to the small dielectric constant of the matrix surrounding NPLs. The thickness dependence of the binding energies of optically active S—exciton states calculated in CdSe NPL are shown in Fig. 10C (Benchamekh et al., 2014). One can see that the binding energy of the 2D exciton, E_{ex}^{2D} in a 1 nm thick NPL could be as large as 250 meV (Benchamekh et al., 2014). The optical gap of CdSe NPLs can be found as:

$$\hbar\omega_{NP} = E_{g,e-hh}^{2D}(1) - E_{ex}^{2D} \quad (14)$$

where $E_{g,e-hh}^{2D}(1)$ is defined in Eq. (13). The calculated size dependence of the optical gap in CdSe NPLs is shown in Fig. 10B by the red line, together with experimental measurements of this gap in different NPL samples. The comparison shows an excellent agreement between theory and experiment (Benchamekh et al., 2014).

One dimensional excitons in nanorods and nanowires

The optical properties of NRs and nanowires are controlled by the spectra of the one-dimensional excitons. Due to the very large binding energy of the 1D excitons, enhanced by the small dielectric constant of the matrix, the optical gap of these structures is significantly smaller than the effective gap for free carriers measured in STM experiments. The difference from NPLs is that the energy

Fig. 10 Effect of dielectric confinement on the electron and hole self-interaction and exciton binding energy in NPLs. A—The thickness dependence of self-interaction energies in CdSe NPLs for lowest levels of electrons, heavy holes and light holes. B—The thickness dependence of the free carrier energy gap, 1S exciton optical energy and 1S and 1P optical transition energies in CdSe NPLs. The experimental data of the optical energy gap measurement are shown by black filled circles. C—The thickness dependence of the binding energies of the $1S_{ex}$ ground and higher nS_{ex} optically allowed exciton states used in the calculation of optical transition energies in Benchamekh et al. (2014). Panel A: Reproduced with permission from Ji Botao, Eran Rabani, Alexander L Efros, Roman Vaxenburg, Or Ashkenazi, Doron Azulay, Uri Banin, Oded Milo (2020) Dielectric confinement and excitonic effects in two-dimensional nanoplatelets. *ACS Nano* 14: 8257–8265 (Copyright 2020 American Chemical Society). Panel B: Reproduced with permission from Benchamekh R, Gippius NA, Even J, Nestoklon MO, Jancu J-M, Ithurria S, Dubertret B, Efros AL, Voisin P (2014) Tight-binding calculations of image-charge effects in colloidal nanoscale platelets of CdSe. *Physical Review B* 89: 035307 (Copyright 2014 American Physical Society).

of electron and hole sublevels in NRs and nanowires are described by Eq. (3) instead of Eq. (2). The full analyses of experimental data conducted in CdSe NRs by Katz et al. (2002) and PbSe NRs by Bartnik et al. (2010), that takes into account the complex band structures and nonparabolicity of these semiconductors and dielectric confinement effects show very good agreement between theory and experiment for both materials (see Shabaev and Efros, 2004 and Bartnik et al., 2010, respectively).

It is interesting to note that one dimensional excitons control also optical properties of monoatomic carbon chains. This system represents ultimate nano-wires where a carbon chain behaves as a direct gap semiconductor and shows narrow exciton and trion resonances in low-temperature photoluminescence spectra (Kutrovskaya et al., 2020, 2021).

Photoluminescence of excitons in nanoscale semiconductor structures

Exciton photoluminescence (PL) in nanostructures is controlled by their fine structure, created by the exchange interaction between electron and hole spins. The electron-hole exchange interaction splits the spin degenerate ground exciton state into an optically allowed (bright) and optically forbidden (dark) exciton sublevels (Efros et al., 1996). In practically all bulk semiconductors and all existing semiconductor heterostructures, the ground exciton state is an optically passive “dark” exciton. The direct optical excitation of this state by a single photon, or its direct photon emission, is forbidden due to the parallel alignment of the electron and hole spin states caused by the ferromagnetic character of the electron–hole exchange interaction. Only exciton states with antiparallel alignment of electron and hole spins (“bright” exciton states) can be excited directly by a photon and directly emit a photon. The only known exception to this rule was reported recently by Becker et al. (2018), in which it was proposed that 10–15 nm size lead-halide perovskite NCs have a bright ground exciton state.

In bulk semiconductors, (Knox, 1963) epitaxial quantum wells, (Kusrayev et al., 1997) and quantum dots, (Bayer et al., 2002; Smoleński et al., 2012; Korkusinski and Hawrylak, 2013) the dark-bright exciton splitting is usually smaller than the thermal energy, even at helium temperature. This results in equal populations of all band-edge exciton levels and a decrease of the total radiative recombination rate of these semiconductors and semiconductor structures by the ratio of the number of bright-emitting exciton states to the total number of the band-edge exciton states. This is not the case, however, for small-size colloidal NCs, NRs, and NPLs, in which the strong spatial confinement leads to dark-bright exciton splitting on the order of dozens of meVs (Nirmal et al., 1995; Efros et al., 1996; Chamarro et al., 1996; Korkusinski et al., 2010; Shabaev and Efros, 2004; Biadala et al., 2014) and the slow radiative recombination of the dark exciton affects the PL, even at room temperature. The absolute majority of investigations of the exciton fine structure were conducted in CdSe NCs. That is why we will mainly focus on the band edge excitons in the heavily studied CdSe NCs and only briefly will discuss exciton fine structure in NRs, and NPLs and other materials.

The optically passive dark exciton was discovered by Bawendi et al. (1990) when the resonance excitation of the PL line of 3.2 nm diameter CdSe NCs showed a significant Stokes shift of the PL and microsecond decay time at helium temperatures. These data were later explained within the dark/bright exciton model, which explained also the magnetic field dependence of the PL fine structure observed under resonant excitation (Nirmal et al., 1995; Efros et al., 1996). The starting point of the model is the assumption of a spherical NC symmetry. In spherically symmetric CdSe NCs (meaning spherical-shaped NCs with a cubic lattice structure), the electron ground $1S_e$ level is doubly degenerate with respect to its spin projection, $s_z = \pm 1/2$, and the hole ground $1S_{3/2}$ level is fourfold degenerate with respect to projections $M = 3/2, 1/2, -1/2$, and $-3/2$ of its total angular momentum, F ($F = 3/2$) (Efros and Rodina, 1989; Ekimov et al., 1993). As a result, the absorption band edge and the PL of these NCs is determined by the $8 = 2 \times 4$ optical exciton transitions between these lowest electron and hole levels. The electron-hole exchange interaction splits the eightfold degenerate exciton state in spherical NCs into a ground optically passive (dark) fivefold degenerate state with a total momentum $\mathcal{F} = 2$ and an upper optically active threefold degenerate state with $\mathcal{F} = 1$. The short- and long-range contributions to this splitting $4\eta_{1S_{3/2}1S_e}^{SR}$ and $4\eta_{1S_{3/2}1S_e}^{LR}$ as it is shown in Fig. 11 (Sercel and Efros, 2018). Both contributions to the e - h exchange interactions are inversely proportional to the NC volume $\sim 1/a^3$, and could be as large as dozens of meVs.

In addition, the spherical symmetry of NCs can be broken by the internal hexagonal crystal field in semiconductors with wurtzite structure (such as CdSe) and the nonspherical, ellipsoidal shape of NCs. These two effects split $M = \pm 3/2$ and $\pm 1/2$ into so-called "heavy" and "light" hole sublevels. The splitting is described by Efros et al. (1996) as $(\Delta/2) [5/4 - M^2]$, where the total splitting $\Delta = \Delta_{int} + \Delta_{sh}$ is the sum of the splitting caused by the hexagonal field, Δ_{int} , and by the NC shape, Δ_{sh} . The anisotropy finally leads to five band-edge exciton states, $\mathcal{F}_z = \pm 2, \pm 1^L, 0^L$ with different projections, $\mathcal{F}_z = M + s_z$, on the hexagonal c -axis of the NC. The complete theory of exciton fine structure that valid for II-VI and III-V compound NCs was developed by Sercel and Efros (2018) and was applied to CdSe NCs. A schematic structure of the exciton sublevel is shown in Fig. 11.

Detailed investigations of the exciton fine structure were conducted for CdSe NRs by Shabaev and Efros (2004). These calculations also explain the linear polarization of PL observed in these nanostructures. The fine structure and polarization properties of the excitons were described theoretically for CsPbBr₃ NCs in Sercel et al. (2019). Recently, a huge (up to 35 meV) dark-bright exciton splitting was measured in CsPbBr₃ NPs, and quantitatively described using a multiband effective mass theory of electron-hole exchange interaction in Gramlich et al. (2021).

Fig. 11 The schematic diagram of the exciton fine structure in CdSe NCs. The diagram shows how the eightfold degenerate $1S_{3/2}1S_e$ exciton in spherical NCs is split by short- and longrange exchange interaction into the optically passive (dark) exciton state with total momentum 2 (shown by dashed line) and a optically active (bright) exciton state with total momentum 1 (shown by solid line). The crystal field and shape asymmetry further split the eightfold exciton into 5 exciton sublevels and activate the lowest exciton state $\pm 1^L$ with angular momentum projection on the hexagonal axis ± 1 . Reproduced with permission from Sercel PC, Efros AL (2018) Band-edge exciton in CdSe and other II-VI and III-V compound semiconductor nanocrystals—revisited. *Nano Letters* 18: 4061–4068 Copyright 2018 American Chemical Society.

Conclusion

All nanoscale semiconductor structures are building blocks for novel bottom-up composite materials, that is why their research and development continues with strong momentum. This is a true interdisciplinary field, at the mutual junction of chemistry, physics, and materials science. The tunability of their optical properties controlled by excitons is, so far, the main application of these structures. The field is not yet mature, and hundreds of scientists and engineers are working on improving synthesis, novel structures, and prototype devices.

In addition to the previously mentioned production of quantum dot TVs based on InP NCs, systematic and persistent synthetic efforts have also created nearly perfect photoluminescence properties in CdSe based core/shell NCs, with quantum yields of 80–95% at room temperature (see Zhou et al., 2017). The use of II-VI alloy compositions has lowered the Cd content in some structures to an acceptable level for commercial use. CdSe based NCs are used in some TVs and displays, in addition to the InP NCs. Within the past 2 years, Osram has begun to use CdSe-based luminescent NCs in GaN LED chips for area (i.e., ceiling) lighting, creating white light of variable designed properties. The success of these efforts depends largely on the continued chemical progress in NC quality and assembly processing, which have shown significant progress in the past decade.

Abstract

The search for Bose-Einstein condensation of long-lived excitons decoupled from the radiation field in bulk semiconductor cuprous oxide is presented. The condensate, which was not confirmed for about 60 years since its theoretical prediction, has been finally observed experimentally. This was achieved by developing a method for the quantitative evaluation of the density and temperature of dark excitons, as well as the cooling to the 100 mK region that proved necessary because of the density-dependent loss. Notably, the discovered exciton condensate exhibits features that have not yet been elucidated, and it is a genuinely new physical system that may exhibit the characteristics of non-equilibrium open systems of quantum many-body Bose particles.

Key points

- Elucidation of the properties of long-lived exciton states in bulk semiconductor Cu_2O .
- Summary of historical aspects of the search for exciton BEC in Cu_2O .
- Explanation of the need for cooling to sub-Kelvin temperatures.
- Summary of the recent discovery of exciton BEC using mid-infrared absorption imaging.

Introduction

The photoexcitation of a semiconductor crystal creates excitons. Excitons are hydrogen-like quasiparticles comprising an electron in the conduction band and a hole in the valence band. Excitons often have short lifetimes due to radiative recombination, but in carefully selected systems, radiative recombination is prohibited or weakly allowed, resulting in relatively long lifetimes. Such exciton systems decoupled from the radiation field are purely matter-like physical systems generated in solids and closely resemble positronium atoms. An exciton comprises a pair of fermions. Therefore, an ensemble that reaches quasi-thermal equilibrium is expected to exhibit Bose-Einstein condensation (BEC) under low-temperature and high-density conditions (Blatt et al., 1962). However, since excitons are elementary excitations in the many-body electron system of semiconductors, there is a limit to treating excitons as composite bosons. Therefore, the appearance of the BEC state itself is not apparent. It is also unknown whether the BEC behaves as a quantum fluid when generated. This problem also encompasses fundamental issues, such as understanding the mass of quasiparticles and how we should quantify the spontaneous breaking of gauge symmetry, which is considered essential also in the BCS theory of superconductivity. Therefore, the experimental observation of spontaneous BEC formation of excitons in bulk semiconductors has been regarded as a holy grail in many research fields, such as solid-state spectroscopy and nonequilibrium quantum statistical mechanics. Here, we will introduce the history of the attempts to realize exciton BECs, which took several twists and turns, mainly from an experimental standpoint.

Excitons in cuprous oxide

The exciton system in bulk cuprous oxide (Cu_2O) is a representative example of a Wannier-Mott exciton, and the discovery of the famous hydrogen-like absorption spectrum was made in Cu_2O (Hayashi and Katsuki, 1950, 1952; Gross and Karryev, 1952a, 1952b). The search for exciton BECs in Cu_2O is only possible because of the rich and solid physics established by many researchers in the past. In the direct-gap semiconductor Cu_2O , the lowest energy conduction band derives from the 4s orbital of Cu, and the highest energy valence band derives from the 3d orbital of Cu (Elliott, 1961). Therefore, 1s excitons are optically forbidden (parity

forbidden) and have very long radiative recombination lifetimes. In addition, these bands have no orbital degeneracy, and the exciton has a simple electronic structure. The 1s exciton state is fourfold degenerate, taking the spin degrees of freedom into account. Because of the exchange interactions between electrons and holes, it splits into a triple degenerate orthoexciton and a non-degenerate paraexciton (the energy splitting is 12 meV). Because the exciton binding energy is large (151 meV for the 1s paraexciton), 1s excitons are stable. The considerable electron-hole exchange interaction prevents the formation of exciton molecules that require spin recombination. In addition, because Cu₂O is a direct-gap semiconductor, no electron-hole droplets are produced, implying that excitons can be maintained at high densities and low temperatures.

In the case of the 1s orthoexciton state, the optical transition from the crystal ground state to the exciton state is dipole-forbidden, but electric quadrupole transitions are allowed. The lifetime is about 3 ns at 2 K. By contrast, the 1s paraexciton state is composed of pure spin triplets; therefore, the optical transition to the ground state of the crystal is completely forbidden. Hence, the lifetime is extremely long. For example, the lifetime of 1s paraexcitons in a high-purity natural single crystal has been reported to be in the microsecond range (Mysyrowicz et al., 1979). Therefore, both the 1s ortho- and paraexciton systems can reach thermal equilibrium with the lattice system within their lifetimes. This means that a sufficiently low-temperature exciton system can be prepared by cooling the crystal. For this reason, the 1s exciton system in Cu₂O has attracted much attention as the most promising candidate for realizing exciton BECs.

Early experiments

The critical density n_c of the BEC transition in a 3-dimensional ideal Bose particle system as a function of temperature T is

$$n_c = 2.612 \left(\frac{m_{1s} k_B T}{2\pi \hbar^2} \right)^{\frac{3}{2}}.$$

Substituting the effective mass of the exciton $m_{1s} = 2.6m_0$ (Brandt et al., 2007, m_0 is the electron mass at rest) into this expression, the BEC transition density is $n_c = 8 \times 10^{16} \text{ cm}^{-3}$ at a superfluid liquid helium temperature of $T = 2 \text{ K}$. A high-density excitation with a pulsed laser can be employed to prepare 1s excitons of this density. Exciton BEC is expected to occur if we wait for the exciton system to cool through interaction with the 2 K lattice. This naive consideration suggests that experimental confirmation of exciton BEC in Cu₂O is feasible.

The analysis of the spectral shape of the LO-phonon-assisted luminescence is conventionally used to experimentally evaluate the thermal distribution function of the translational motion of 1s excitons. In early experiments, nanosecond laser pulses were used to generate high-density electrons and holes near the crystal surface by band-to-band excitation, and subsequent time-resolved emission measurements were performed. Researchers reported many important phenomena, such as the observation of a change in the distribution function from the classical Maxwellian to the quantum degenerate Bose-Einstein distribution; a “quantum saturation” (Snoke et al., 1987) phenomenon in which 1s orthoexcitons stay just before the BEC phase boundary; and a peculiar thermal distribution suggestive of the BEC of 1s paraexcitons (Fig. 1, Snoke et al., 1990a, 1990b).

Fig. 1 Typical LO-phonon-assisted luminescence spectra of 1s orthoexcitons (left) and 1s paraexcitons (right) that suggest the generation of quantum degenerate gas of 1s excitons. The time-resolved luminescence spectra were recorded under a 10-ns, near-surface pulsed excitation at 2 K. Both exciton species can be fitted well with the Bose-Einstein distribution function, which allowed authors to evaluate the density and the temperature of the gasses. When 1s paraexcitons satisfied the BEC criterion, a “bump” structure appeared. From Snoke DW, Wolfe JP, Mysyrowicz A (1990a) Evidence for Bose-Einstein condensation of a two-component exciton gas. *Physical Review Letters* **64**: 2543–2546.

Fig. 2 Time-resolved photovoltaic signal under a 10-ns laser pulse irradiation at 532 nm. Initially, high-density excitons were generated near the surface, which was 3.56 mm away from the electrodes. Since the photovoltaic signal originates from excitons that dissociate because of a built-in voltage near the electrodes, the time-resolved signal reflects the propagation of the excitons across the 3.56-mm thickness of the Cu_2O crystal. A sudden change from diffusive to ballistic propagation appeared when the lattice temperature decreased. Similar behavior was confirmed when the excitation intensity was increased at a constant lattice temperature. The ballistic propagation velocity was nearly equal to the longitudinal sound velocity of the crystal. From Fortin E, Fafard S, Mysyrowicz A (1993) Exciton transport in Cu_2O : Evidence for excitonic superfluidity? *Physical Review Letters* **70**: 3951–3954.

In addition, time-resolved observations of exciton-mediated currents under similar experimental conditions revealed ballistic propagation signals that suggested exciton superfluidity (Fig. 2, Fortin et al., 1993). Although a conclusion was seemingly reached regarding the observation of BEC of excitons, questions still remained. For example, the emission of paraexcitons is extremely weak, which raised concerns about the reliability of the lineshape analyzes. In addition, the ground-state component with zero kinetic energy was absent from the luminescence spectrum. In particular, the lack of quantitiveness of the exciton density was fatal to the evidence for BECs.

The ballistic photovoltaic signals discussed above are remarkable. Nevertheless, quantitative information on exciton density and temperature is lacking. Therefore, it is still unknown whether this phenomenon is correlated with exciton BECs. Another explanation for this propagation is the so-called phonon wind phenomenon (Kopelevich et al., 1996), which is unrelated to quantum condensation. Thus, the quantitative evaluation of 1s excitons, particularly the density, became an important aspect of elucidating the mechanism underlying many of the interesting phenomena mentioned previously.

Collision-induced loss

For 1s orthoexcitons, a relatively bright emission signal can be obtained. Through careful experiments, researchers determined the number of 1s orthoexcitons created in a crystal from the light intensity by evaluating the quantum efficiency of the detection system (O'Hara et al., 1999). They found that the gas is orders of magnitude more dilute than the exciton density that can be evaluated from shape analyses of the emission spectrum. The decrease in density is due to a density-dependent nonradiative recombination process, wherein one of the excitons disappears in the two-body collisions between excitons. The two-body process accelerates the other exciton that survives. The effective lifetime of the exciton τ_{eff} is then

$$1/\tau_{\text{eff}} = An$$

(A is the two-body scattering coefficient and n is the exciton density). They found that the collision coefficient is extremely large, i.e., approximately $A = 10^{-16} \text{ cm}^3/\text{ns}$. They also showed that the spectral shape of the quantum degenerate Bose-Einstein distribution is actually the result of a superposition of classical distributions such that the temperature and density are high near the surface and low inside the crystal (O'Hara and Wolfe, 2000). The experimentally observed temperature corresponding to the Bose-Einstein distribution was considerably higher than the lattice temperature, supporting the scenario. Thus, researchers revealed that the 1s orthoexcitons remain classical by quantitatively evaluating the exciton density (Fig. 3).

The physical mechanism of the aforementioned two-body scattering-induced loss is currently unknown. A similar process called the exciton Auger process is well-established, although the theoretical scattering coefficient is orders of magnitude smaller than the actual one (Kavoulakis and Baym, 1996; Kavoulakis and Mysyrowicz, 2000).

With the possibility of quantum degeneracy of 1s orthoexcitons denied, researchers focused on quantifying the density of 1s paraexcitons and the magnitude of the two-body loss rate. However, the intensity of the LO-phonon-assisted luminescence of the

Fig. 3 Simulated LO-phonon-assisted luminescence spectrum of 1s orthoexcitons assuming spatially inhomogeneous Maxwell-Boltzmann distributions (solid curves). Dashed curves are Bose-Einstein distribution functions, intentionally displaced vertically. Both curves well explain the experimental luminescence spectra, but the simulated ones provide a better fit, particularly on the high-energy side of the spectra. From O'Hara KE and Wolfe JP (2000) Relaxation kinetics of excitons in cuprous oxide. *Physical Review B* **62**: 12909–12922.

1s paraexciton state is about three orders of magnitude weaker than that of orthoexcitons. Therefore, the quantitative evaluation of 1s paraexcitons through luminescence experiments is nearly impossible.

Excitonic Lyman spectroscopy

Researchers began to develop an alternative spectroscopic method to detect the density and temperature of 1s paraexcitons quantitatively. In principle, excitons in the 1s state can be excited to the p-series excited states with higher principal quantum numbers, i.e., 2p, 3p, 4p, etc., because of the hydrogen-like energy structure (Nikitine, 1984). These transitions, called excitonic Lyman transitions, are strongly electric dipole allowed. The transitions change the relative motion of an electron and a hole; therefore, they are spin-independent and function for both ortho- and paraexcitons. Therefore, relatively dilute excitons can be detected with high sensitivity. Furthermore, because of central-cell corrections, the effective mass of the 1s exciton is heavier than that of other exciton states. Therefore, the energy distribution of the translational motion of the 1s excitons is reflected in the spectrum of excitonic Lyman transitions. Several research groups succeeded in detecting the 1s-2p transitions located in the mid-infrared wavelength range in the early 2000s (Kuwata-Gonokami et al., 2004; Jörger et al., 2005; Fishman et al., 2006).

Under the quantitative evaluation of the paraexciton density using the 1s-2p transition with a resonance at 128 meV (wavelength of 9.6 μm), experiments were performed to evaluate the two-body scattering-induced loss coefficient and its temperature dependence. It was found that the two-body loss coefficient for the 1s paraexciton is as large as that for the 1s orthoexcitons reported in O'Hara et al. (1999), which is about $A = 10^{-16} \text{ cm}^3/\text{ns}$, and that the coefficient is independent of temperature (Yoshioka et al., 2010). The result means that even if the BEC critical density of 10^{17} cm^{-3} at 2 K is realized, the effective lifetime is only 0.1 ns instead of being in the microsecond range. Considering that the cooling time of 1s paraexcitons because of the exciton-phonon interaction with the lattice is several nanoseconds, the exciton temperature remains much higher than 2 K. Furthermore, the high excitation powers required to compensate for the collisional annihilation and maintain a high density, as well as the resultant heat generation in the crystal, render the realization of BECs at 2 K impossible (Fig. 4).

From (Yoshioka et al., 2010)

Fig. 4 (left) Typical 1s-2p induced absorption spectrum of paraexcitons in the quasi-steady-state, measured under a quasi-continuous-wave excitation. 1s orthoexcitons were generated via the phonon-assisted absorption process, and subsequently, the orthoexcitons were spontaneously converted into 1s paraexcitons. The 1s-2p transition resonance is located in the mid-infrared wavelength region. A tunable carbon dioxide laser was used because the oscillation wavelengths accidentally coincided with the resonance. The spectrum reflects the thermal distribution of 1s paraexcitons, and one can measure the absolute paraexciton density from the spectral area. The oscillatory structure originates from the Fabry-Perot interference effect of the 220- μm thick natural single crystal used in the experiment. (right) Measured paraexciton density as a function of the generation rate of orthoexcitons. The paraexciton density shows a sublinear dependence when the density is well below the BEC transition density at 2 K, implying that the nonlinear loss process is efficient. The solid curves are simulated results in which the two-body collision loss coefficient A is considered an adjustable parameter. From Yoshioka K, Ideguchi T, Mysyrowicz A, Kuwata-Gonokami M (2010) Quantum inelastic collisions between paraexcitons in Cu_2O . *Physical Review B* **82**: 041201(R).

Experiments at sub-Kelvin temperatures

To achieve BECs, the frequency of scattering-induced losses must be reduced. Because the mechanism of the density-dependent exciton loss and methods of controlling it are unknown, the only way to satisfy the BEC criterion is to lower the exciton temperature and set the BEC critical density to a lower value. Several research groups initiated experiments to cool semiconductor crystals to sub-Kelvin temperatures to satisfy the BEC criteria. Because it is expected to take more than several nanoseconds for an exciton gas to attain thermal equilibrium with the lattice below 2 K, the 1s paraexciton state is the only option.

It is well-established that 1s paraexcitons diffuse ballistically on the millimeter scale within their lifetime at low temperatures (Trauernicht et al., 1984; Trauernicht and Wolfe, 1986). The rapid diffusion can be avoided by forming a three-dimensional trap by applying inhomogeneous stress via a Hertzian contact (Trauernicht et al., 1983; Trauernicht et al., 1986; Snoke and Negoita, 2000; Naka and Nagasawa, 2002, 2004, 2005; Sandfort et al., 2011). The trap acts as a harmonic potential for excitons at low temperatures, and the number of excitons N_c required for the BEC transition in the trap is

$$N_c = 1.2 \left(\frac{k_B T}{\hbar \bar{\omega}} \right)^3,$$

where $\bar{\omega}$ is the geometric mean of the trap frequencies. The critical number is proportional to the cube of the temperature. Therefore, it is feasible to satisfy the BEC condition by a quasi-steady-state excitation using a continuous-wave laser and accumulating long-lived paraexcitons, even with the limited cooling capacity of a refrigerator.

In 2011, a BEC transition of trapped 1s paraexcitons at an exciton temperature of 800 mK was reported by using a ^3He refrigerator to cool a Cu_2O crystal to 354 mK (Yoshioka et al., 2011). The BEC critical density at 800 mK is $n_c = 1.9 \times 10^{16} \text{ cm}^{-3}$, and the corresponding number of exciton is $N_c = 7.6 \times 10^8$. The experiment observed the spatially resolved luminescence spectrum of thermal paraexciton components because the direct recombination process is weakly allowed under a finite strain field. When the BEC criterion was met, a threshold-like rise of exciton components with high kinetic energies was found. This phenomenon is a “relaxation explosion” associated with the BEC transition. In this case, the condensate is unstable. In a harmonic potential, macroscopic occupation of the ground state wavefunction results in high-density excitons, followed by the aforementioned frequent two-body collision-induced loss process. The relaxation process was originally introduced to the BEC of atomic hydrogen in a magnetic trap, which decays rapidly because of enhanced inelastic two-body collisions induced by the density increase associated with the condensate formation (Fig. 5).

To achieve stable condensates, the BEC transition density must be further reduced; i.e., the exciton temperature must be lowered. Two research groups in Japan and Germany performed experiments using dilution refrigerators (Stolz et al., 2012; Yoshioka et al., 2013; Morita et al., 2019). 1s paraexcitons are cooled via the emission of LA phonons. However, the exciton temperature cannot be

Fig. 5 Relaxation explosion of 1s paraexcitons accumulated in a strain-induced trap potential. When the number of paraexcitons is below the critical number, the spatially resolved luminescence spectrum suggests that the gas is in a quasi-equilibrium state with an exciton temperature of 800 mK. A hot exciton component appeared in a threshold-like manner when the number of excitons exceeded the critical number for BEC. The sudden increase of the hot component also occurred by decreasing the lattice temperature while maintaining the trapped number of paraexcitons constant. From Yoshioka K, Chae E, Kuwata-Gonokami M (2011) Transition to a Bose-Einstein condensate and relaxation explosion of excitons at sub-Kelvin temperatures. *Nature Communications* 2: 328.

reduced below 1 K, irrespective of the crystal temperature. This limitation originates from the dispersion relations of LA phonons and paraexcitons and the conservation law of energy and momentum. However, the crystal symmetry is reduced under a finite strain field, and the interaction between 1s paraexcitons and TA phonons is activated. The sound velocity of the TA phonon is slower than that of the LA phonon, and the activation of the additional cooling channel results in an unprecedentedly low exciton temperature of 100 mK (Yoshioka et al., 2013) (Fig. 6).

Following being cooled to the 100 mK temperature region, the 1s paraexciton exhibits a very low interaction rate with phonons. Therefore, the motion of the para exciton approaches that of a ballistic one with little scattering. In fact, high diffusion coefficients

Fig. 6 Applied stress dependence of the luminescence spectrum of 1s paraexcitons in a strain-induced trap potential. The lattice temperature was 40 mK, and the excitation power was maintained as low as 4 nW to preclude heating effects and find the lowest possible exciton temperature. When the stress was increased from (a) 1.0 kbar to (c) 2.7 kbar, the paraexciton temperature dropped from 207 ± 33 mK to 97 ± 33 mK. This is the lowest exciton temperature achieved to date in bulk semiconductors. The stress dependence demonstrates that the cooling channel via transverse acoustic phonons is activated in strain-induced trap potentials. From Yoshioka K, Morita Y, Fukuoka K, Kuwata-Gonokami M (2013) Generation of ultracold paraexcitons in cuprous oxide: A path toward a stable Bose-Einstein condensate. *Physical Review B* **88**: 041201(R).

and mobilities, which have never been observed in bulk semiconductors previously, are observed in time- and space-resolved luminescence measurements (Morita et al., 2019). This means that a clean system is prepared in which the spatial distribution of the ensemble is defined by the designed strain-induced trapping potential and exciton-exciton interactions, almost unaffected by scattering from phonons, lattice defects, and impurity sites in the crystal. In high-density conditions, however, the two-body collision-induced loss process can accelerate paraexcitons, and therefore, continuous cooling by the cold phonon bath should play an essential role in the global behavior of the exciton ensemble.

In bulk semiconductors, both quantum degenerate exciton states at such a low temperature and condensates cannot be detected by conventional luminescence measurements. This is because the exciton momentum is extremely small, such that excitons cannot supply the photon momentum in the radiative recombination process. Instead, mid-infrared absorption imaging of excitons using the 1s-2p transition of paraexcitons (Yoshioka and Kuwata-Gonokami, 2015) has been applied to dilution refrigerator experiments, and a threshold-like appearance of condensates at the bottom of a trap was finally observed at a peak density on the order of 10^{15} cm^{-3} (Morita et al., 2022).

Morita et al. (2022) have shown that the spatial spread of the condensate in the ground state of the trap broadens as the number of excitons in the condensate increases. This behavior can be described based on the Gross-Pitaevskii equation, as in the case of weakly interacting dilute atomic gases. The elastic scattering length between 1s paraexcitons was extracted based on this expanding behavior. The results were consistent with the theoretical scattering length evaluated by quantum Monte Carlo calculations (Shumway and Ceperley, 2001). In this manner, the conventional understanding of condensates can describe some phenomena, whereas other behaviors cannot be understood. The best example is the small condensate fraction. The maximum condensate fraction is only 1.6%, although the interparticle interaction is significantly weaker than in liquid helium. This feature cannot be explained in the framework of conventional theories and may correspond to the characteristics of quantum condensates in nonequilibrium open systems (Fig. 7).

Conclusion

The observation of spontaneous BEC of excitons in bulk semiconductors has proved that purely matter-like quasiparticles, decoupled from the radiation field, form a macroscopic quantum state. Consequently, the research field of many-body and low-temperature exciton systems has entered a new stage. This type of BECs constitutes a new state beyond the framework of conventional theories and is expected to provide an opportunity to profoundly deepen our understanding of the physics of the spontaneous formation of quantum coherence under various dissipation channels in the environment of a solid. Furthermore, the quasi-equilibrium state of the exciton system is formed by contact with a thermal bath, that is a cold phonon system, rather than by elastic scattering between excitons; therefore, it is also important as one of the physical systems that exhibit the interaction-free phase transitions envisioned by Einstein. Elucidating the following phenomena will be the key to a detailed description of this physical system and will help promote further research in this field:

- Observation of the dynamics of condensate formation through the time-resolved absorption imaging of trapped paraexcitons.
- Evaluation of the second-order spatial coherence.

Fig. 7 Visualization of a Bose-Einstein condensate of 1s paraexcitons in a strain-induced trap potential using the mid-infrared absorption imaging technique. Macroscopic occupation at the trap bottom was found, and its density exceeded the BEC critical density at the measured exciton temperature of 170 mK. The spatial spread of the condensate increases through the exciton-exciton elastic interactions, which can be described by the Gross-Pitaevskii equation similarly to weakly-interacting cold atomic gases. However, the small maximum condensate fraction of 1.6% is a newly discovered and unexplained phenomenon. From Morita Y, Yoshioka K, Kuwata-Gonokami M (2022) Observation of Bose-Einstein condensates of excitons in a bulk semiconductor. *Nature Communications* **13**: 5388.

- Elucidation of the behavior of condensate fractions at low exciton temperatures.
- Measurements of the conversion rate from 1s orthoexcitons produced by laser excitation to 1s paraexcitons in the 100 mK temperature region.
- Elucidation of the physical mechanism of two-body collision-induced exciton loss and the development of control methods.
- Development of a method for growing single crystals of Cu_2O with high purity. The density of lattice defects is generally considered to limit the paraexciton lifetime because the radiative lifetime is considerably longer than the actual lifetime of around one microsecond. In addition, if impurities or defect sites are involved in the exciton-exciton collision-induced losses, the high-purity crystals may dramatically simplify exciton BEC experiments.
- Evaluation of the relevance of condensation phenomena observed in two-dimensional physical systems, particularly long-lived exciton systems in coupled quantum wells that are weakly coupled with the radiation field and cavity exciton-polaritons that are strongly coupled to the radiation field.

Abstract

The characteristic aspect of the optical properties of nanostructures is described with an emphasis on the size and shape dependence of optical responses, in contrast to that of macroscopic systems. The microscopic treatment for the theoretical description of such systems is outlined, which requires nonlocal relationship between light field and induced polarization, allowing one to treat the regime beyond long wavelength approximation (LWA). The radiative shift and width, which are system-specific, are shown to play an important role in nanostructures. The effect of microcavity is also discussed in terms of renormalized radiation Green function, which allows for a systematic description within the microscopic nonlocal scheme. Examples of the experimental observation reflecting characteristics of optical responses of nanostructures, in particular, for the beyond-LWA regime are shown.

Key points

- One of the remarkable aspects of nanostructures is the explicit dependence of optical response on the size, shape, and internal structure due to quantum mechanically confined electronic systems.
- The nonlocal response is the key concept to providing a good overview and technical ease based on the first-principles formulation of light-matter interaction in nanostructures.
- The microscopic nonlocal response theory provides self-consistent solutions containing the radiative corrections (shift and width) with dependence on the size, shape, and internal structure.
- The mode structure modification of the electromagnetic field of the cavity effect can be included in the microscopic nonlocal theory through the electromagnetic Green function of the background and/or environmental medium.
- Typical phenomena characterized by the nonlocal response, where the spatial variation in the electric field is remarkable, have been observed as a large optical nonlinearity and an ultra-fast response of non-dipole type excited states in various types of experiments.

Nomenclature

$X_{\mu\nu}$	Another expansion coefficient of induced polarization
ϵ_b	Background dielectric constant
ξ, η	Cartesian coordinates
$J(r, \omega)$	Current density at position r with frequency ω

[☆]*Change History:* April 2015. H Ishihara added the section “Examples of Observed Phenomena”, and “References”. January 2022. H. Ishihara added some descriptions and references in the section “Examples of Observed Phenomena”.

ϵ_0	Dielectric constant of vacuum
$\hat{P}(\mathbf{r})$	Electric dipole density operator
$E(\mathbf{r}, \omega)$	Electric field at position $\mathbf{r}$ with frequency ω
E_b	Electric field induced by the scattering of an incident field from background dielectric alone
E_v'	Energy eigenvalue including the screening effect of the background dielectrics
E_ν	Energy of the ν -th eigenstate of matter, $\nu = 0$ for the ground state
$F_{\mu\nu}$	Expansion coefficient of induced polarization
G_b	Green function describing the propagation of EM field in the presence of background dielectric
G_{cp}	Green function describing the propagation of EM field of cavity polariton
Θ	Heaviside function to describe the size and shape of background dielectric
$\chi^{(1)}$	Linear polarizability
P_{NL}	Nonlinear part of induced polarization
χ_b	Polarizability of background dielectric
$P(\mathbf{r}, \omega)$	Polarization at position $\mathbf{r}$ with frequency ω
$\mathcal{A}^{(b)}$	Radiative interaction energy between the components of induced polarization via the EM field of background dielectric
$\mathcal{A}_{\mu 0, 0\nu}(\omega)$	Radiative interaction energy between the matter citations ($0 \rightarrow \mu$) and ($0 \rightarrow \nu$) via the EM field of frequency ω
P_{res}	Resonant part of induced polarization
$E^{(0)}$	Solution of homogeneous differential equation, usually an incident field inducing polarization
$A(\mathbf{r}, \omega)$	Vector potential at position $\mathbf{r}$ with frequency ω
DBR	Distributed Bragg reflector
EM	Electromagnetic
G	Green function describing the propagation of EM field
LWA	Long wavelength approximation
q	Wave number of light in vacuum ($=\omega/c$)
QED	Quantum electrodynamics
Q-value	Quality factor of a resonance, i.e., resonant frequency divided by resonance width
QW	Quantum well
RWA	Rotating wave approximation
S	Coefficient matrix of the linear equation to determine X

Introduction

The reason for the optical properties of nanostructures to attract special attention is the explicit dependence of optical response on the size, shape and internal structure of a matter, which leads to an additional possibility of controlling materials for various applicational purposes. In view of the importance of the coherence of matter excitations in the description of the optical processes in nanostructures, which has been neglected in the traditional theory for bulk systems, it is worth having a separate item for this subject.

Optical properties of matter is the consequence of the interaction between matter and light (oscillating EM field), which depends sensitively on the space-time structure of the EM field and the induced polarization of the matter. The factors to determine this dependence are the frequency or pulse structure, polarization, and propagation direction of light, and the amplitudes of the induced polarization of matter with various resonance frequencies corresponding to the quantum mechanical level structure of the matter.

The light-matter interaction is fully described by the equations of motion for the dynamical variables of light and matter. As such variables, a usual choice is electric field $E(\mathbf{r}, t)$ and polarization $\mathbf{P}(\mathbf{r}, t)$, but there is another choice, i.e., vector potential of light $\mathbf{A}(\mathbf{r}, t)$ and current density of matter $\mathbf{J}(\mathbf{r}, t)$. The latter is slightly more general, because current density may include magnetic one (proportional to the rotation of magnetization). If we neglect this contribution, $\mathbf{J}(\mathbf{r}, t)$ and $\mathbf{P}(\mathbf{r}, t)$ are simply related as $\mathbf{J} = \partial \mathbf{P} / \partial t$, which applies to most cases of optical response of matter.

The scheme of equations of motion for $\mathbf{A}$ and $\mathbf{J}$ (or E and $\mathbf{P}$) is common to quantum electrodynamics (QED) with quantized EM field and the semiclassical treatments in terms of classical EM field. The difference is whether the vector potential is treated as operator or not. This difference does not always lead to a difference in calculated physical quantities. In QED, photons of each mode are described as a statistical ensemble, while in semiclassical picture EM field of each mode is represented by a complex amplitude corresponding to an average value of photon ensemble. The QED description is absolutely necessary when the physical quantity is related with some details of photon ensemble, or when the optical processes involve the contribution of non-commutative relation of photon creation and annihilation operators. Typical examples will be the squeezed light or various multi-time correlation functions. However, there are many other quantities which can be correctly calculated semi classically i.e., those depending just on the average photon number and phase (of each mode) arising from the optical processes without involving non-commutative terms of photon operators. Examples are the light intensities arising from the linear and nonlinear processes without involving same photon modes in the elementary steps of light-matter interaction.

Another important aspect in optical processes is the microscopic spatial structure in $E(\mathbf{r}, t)$ and $\mathbf{P}(\mathbf{r}, t)$. This has been neglected in macroscopic response theories, and also in QED treating atoms and molecules. In such a treatment, the $\mathbf{r}$ -dependence of EM field is

assumed to be always much weaker than that of induced polarization, so that the latter is represented by its zero-th moment, i.e., the electric dipole moment of the transition,

$$\int d\mathbf{r} \langle \mu | \hat{\mathbf{P}}(\mathbf{r}) | \nu \rangle \quad (1)$$

where μ, ν are the quantum numbers of matter eigenstates. In other words, all the optical transitions are approximated as point-like electric dipoles with various eigenfrequencies and amplitudes in the long wavelength approximation (LWA) for EM field.

Nanostructures have attracted attention because of the size quantized energy levels of matter. The microscopic spatial structure of induced polarization is exactly the counterpart of the energy quantization, so that it is quite consistent to consider these aspects simultaneously in the description of optical response in nanostructures. Every quantum state has its own resonant frequency and the characteristic spatial structure in its induced polarization, which depend sensitively on the size and shape of matter. Though this applies in principle also to atomic and macroscopic systems, it is only in nanostructures that we can easily observe the size- and shape-dependence of optical responses.

Optical properties of matter are usually described in terms of linear and nonlinear polarizabilities (electric susceptibility, or more simply, susceptibility). In macroscopic systems, they are considered to be intensive quantities, i.e., independent of the size and/or shape of matter, which can be derived by the so-called Lorentz oscillator model based on classical mechanics (forced oscillation of harmonic oscillator with damping) under LWA. However, a quantum mechanical calculation of polarizabilities without the use of LWA gives an expression in terms of the energy eigenvalues $\{E_v\}$ and the matrix elements of dipole density operator, a different result from Lorentz model. For example, the linear susceptibility at absolute zero Kelvin is given, in units of ϵ_0 , as

$$\chi_{\xi\eta}^{(1)}(\mathbf{r}, \mathbf{r}', \omega) = \sum_v \left\{ \frac{\langle 0 | \hat{P}_\xi(\mathbf{r}) | v \rangle \langle v | \hat{P}_\eta(\mathbf{r}') | 0 \rangle}{E_v - E_0 - \hbar\omega - i0^+} + \frac{\langle 0 | \hat{P}_\eta(\mathbf{r}') | v \rangle \langle v | \hat{P}_\xi(\mathbf{r}) | 0 \rangle}{E_v - E_0 + \hbar\omega + i0^+} \right\} \quad (2)$$

where $v = 0$ stands for the ground state. The positive infinitesimal (0^+) represents the adiabatic switching of light-matter interaction. When the nonradiative damping of matter excitations needs to be considered, the $\{0^+\}$'s are replaced with the self-energies of the excitations caused by nonradiative scattering, and are often approximated by a phenomenological parameter.

This polarizability, as well as higher order ones, is not an intensive quantity, but a position dependent integral kernel with various resonances appearing as poles of frequency dependent functions. It depends on the size and shape of matter through the resonant frequencies $(E_v - E_0)/\hbar$ and the coupling matrix elements of transitions, which is most conspicuously seen in the range of nano-meters. One of the fundamental problems is the evolution of polarizabilities from size-dependent to size-independent regimes, which is due to the size dependence of (i) the contribution of single quantum states and (ii) the intervals of neighboring quantum states. In the case of nonlinear polarizabilities, the size dependence is deeply related with the so-called cancellation problem.

The dependence of the resonance frequencies, i.e., absorption and/or emission peaks, on the system size and shape is due to the boundary condition for the wave function of each excited state extending coherently over the whole structure. This is understood from an analogy of a particle of mass M confined in a one-dimensional well of size d . The boundary condition restricts the form of its wave function to $\sin(kx)$ and the energy eigenvalue $E = \hbar^2 k^2 / 2M$, with the size-quantized wave number $k = \text{integer} \times \pi/d$.

This allows us to design the optical properties of matter for various aims. Together with the technical development of nano-size fabrication, it has encouraged the studies of applicational aspects of nanostructures. At the same time, this has opened a new phase of fundamental character of matter, in particular of nanostructured materials, where the coherence of matter states plays an essential role. Due to the coherence of the excited state of matter maintained over whole nanostructure, a full quantum mechanical treatment of polarizabilities is required. In other words, the microscopic character of EM field and induced polarization need to be thoroughly considered, which inevitably leads to the nonlocal polarizability. (See the item "Polarizability".)

The nonlocal nature of optical response in microscopic theory means that the cause (EM field) and the result (polarization) may occur at microscopically different spatial points, as far as the points are within the extension of the relevant wave functions. The nonlocality of response is a common feature to all excitations of wave-like character, such as sound, light, and the quantum mechanical excitations described by wave functions.

It may look a complication that polarizabilities become position dependent integral kernels, in comparison with their constant values in macroscopic approach. It is not simply the case, however, because the fact that they are in general separable kernels allows us to rewrite (Maxwell) integral equations into simultaneous polynomial equations, which is certainly easier to handle. In this sense, nonlocal response is a key method to provide a good overview and technical ease, based on the first-principles formulation of light-matter interaction.

Scheme of microscopic response

For a given initial condition of light and matter, the optical response is obtained in the following way. We write the polarization induced by EM field and the EM field produced by polarization, and solve them simultaneously. For nanostructures, it is necessary to do this in terms of the microscopic polarizabilities and without the use of LWA. In view of the importance of resonant processes in nanostructures, which reflect the size and shape dependence sensitively, it is essential to solve the equations self-consistently (simultaneously).

The two sets of equations to be solved, in the case of, e.g., linear response, are

$$P_{\xi}(\mathbf{r}, \omega) = \varepsilon_0 \int d\mathbf{r}' \chi_{\xi\eta}^{(1)}(\mathbf{r}, \mathbf{r}'; \omega) E_{\eta}(\mathbf{r}'; \omega), \quad (3)$$

and

$$E_{\xi}(\mathbf{r}, \omega) = E_{\xi}^{(0)}(\mathbf{r}, \omega) + \sum_{\eta} \int d\mathbf{r}' G_{\xi\eta}(\mathbf{r}, \mathbf{r}'; \omega) P_{\eta}(\mathbf{r}'; \omega). \quad (4)$$

The latter equation is the solution of the Maxwell equations for a given source polarization $P(\mathbf{r}, \omega)$ in terms of the radiation Green function $G(\mathbf{r}, \mathbf{r}'; \omega)$ of vacuum EM field

$$G(\mathbf{r}, \mathbf{r}'; \omega) = \frac{4\pi}{V} \sum_{\mathbf{k}\sigma} \hat{\mathbf{e}}_{\sigma}(\mathbf{k}) \frac{e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')}}{k^2 - (q + i\delta)^2} \hat{\mathbf{e}}_{\sigma}(\mathbf{k}) \quad (5)$$

where $q = \omega/c$ and $\hat{\mathbf{e}}_{\sigma}(\mathbf{k})$ ($\sigma = 1, 2$) are two mutually orthogonal unit vectors perpendicular to $\mathbf{k}$, and $V (\rightarrow \infty)$ is the quantization volume. This Green function describes the propagation of light in vacuum. The initial condition of light (incident light, for example) is represented by $E_{\xi}^{(0)}(\mathbf{r}, \omega)$, and that of matter (usually, the ground state) is included in the susceptibilities. For nonlinear response, we need to add the terms of nonlinear polarizations to the right hand side of Eq. (3). The equations are a closed set for a given frequency ω in the case of linear response, but they are not in nonlinear cases.

The set of integral Eqs. (3) and (4) can be put into a set of simultaneous linear equations for the variables $X_{\mu 0}(\omega) = g_{\mu}(\omega) F_{\mu 0}(\omega)$ and $X_{0\mu}(\omega) = h_{\mu}(\omega) F_{0\mu}(\omega)$, where

$$g_{\mu}(\omega) = \frac{1}{E_{\mu} - E_0 - \omega - i0^+}, \quad (6)$$

$$h_{\mu}(\omega) = \frac{1}{E_{\mu} - E_0 + \omega + i0^+},$$

$$F_{\mu\nu}(\omega) = \int d\mathbf{r} E(\mathbf{r}, \omega) \cdot \langle \mu | \hat{\mathbf{P}}(\mathbf{r}) | \nu \rangle. \quad (7)$$

The solution of such equations gives the polarization P as

$$P(\mathbf{r}, \omega) = \sum_{\nu} \left[X_{0\nu} \langle \nu | \hat{\mathbf{P}}(\mathbf{r}) | 0 \rangle + X_{\nu 0} \langle 0 | \hat{\mathbf{P}}(\mathbf{r}) | \nu \rangle \right]. \quad (8)$$

The simplest version of the linear equations to determine $\{X\}$ is the one in rotating wave approximation (RWA) and is given as

$$F_{\mu 0}^{(0)}(\omega) = \sum_{\nu} [(E_{\nu} - E_0 - \hbar\omega - i0^+) \delta_{\mu\nu} + \mathcal{A}_{\mu 0, 0\nu}(\omega)] X_{\nu 0}(\omega), \quad (9)$$

where

$$F_{\mu 0}^{(0)}(\omega) = \int d\mathbf{r} E^{(0)}(\mathbf{r}, \omega) \cdot \langle \mu | \hat{\mathbf{P}}(\mathbf{r}) | 0 \rangle \quad (10)$$

is a known factor for a given incident light, and the radiative correction $\mathcal{A}$ is defined as

$$\mathcal{A}_{\mu 0, 0\nu}(\omega) = - \int d\mathbf{r} \int d\mathbf{r}' \langle \mu | \hat{\mathbf{P}}(\mathbf{r}) | 0 \rangle \cdot \mathbf{G}(\mathbf{r}, \mathbf{r}', \omega) \cdot \langle 0 | \hat{\mathbf{P}}(\mathbf{r}') | \nu \rangle. \quad (11)$$

This is a complex quantity representing the interaction energy between two induced dipole densities $\langle 0 | \hat{\mathbf{P}}(\mathbf{r}) | \mu \rangle$ and $\langle 0 | \hat{\mathbf{P}}(\mathbf{r}') | \nu \rangle$ via the EM field of frequency ω . The real and imaginary parts of a diagonal term ($\mu = \nu$) represent the shift and width, respectively, of the matter transition energy $E_{\mu} - E_0$. The off-diagonal elements $A_{\mu 0, 0\nu}$ represent the radiative interaction among different matter excitations, giving additional contribution to the radiative shift and width.

The solution of Eq. (9) determines the polarization via Eq. (8) (without the terms $X_{0\nu}$, because of RWA), which further determines the induced field via Eq. (4). In this way, the optical response is determined uniquely from the set of simultaneous linear equations. In the case of nonlinear response, Eq. (3) contains nonlinear terms of factors $F_{\mu\nu}(\omega)$ for various μ, ν and ω , and in this case the equations to be solved are a set of simultaneous polynomial equations of order N , where N is the order of non-linearity in consideration.

In this way of solution, there is obviously no requirement of the boundary conditions for EM field at the surface/interface of matter. This is because the boundary conditions (of matter system) are already taken into account in the expression of polarizability, so that there is no need of boundary conditions for EM field any more. Additional boundary condition (ABC) is neither required when the matter excitations contain the effect of spatial dispersion. In fact, this way of solution is a method developed from an ABC-free formalism to solve confined exciton problems without using ABC.

It should be stressed that the condition $\det |\mathbf{S}| = 0$, where $\mathbf{S} = (E_{\nu} - E_0 - \hbar\omega) \mathbf{1} + \mathcal{A}$, for the existence of non-trivial solution of Eq. (9) in the absence of external field (i.e., $F^{(0)} = 0$), is exactly the resonance condition for X in the presence of the external field. The modes satisfying this condition are the eigenmodes of the coupled light-matter system. They are self-sustaining modes in the sense that they consist of finite amplitudes of E and P in the absence of external excitation. Thus we understand that the resonance in optical spectra appears at the frequency of self-sustaining mode, i.e., matter excitation energy corrected by radiative shift and broadening. When there is translational symmetry in the matter system, the matrix $\mathbf{S}$ is diagonal with respect to the corresponding

wave number, so that $\det |\mathbf{S}| = 0$ holds for each wave number separately, giving dispersion relation $\omega = \omega(k)$. This is a most general dispersion equation for interacting light-matter systems.

The factor X_{v0} contains an energy denominator which diverges at a matter excitation energy $E_v - E_0$, while the factor X_{v0} itself is enhanced, not at $E_v - E_0$, but at the energy corrected by radiative shift. One of the peculiar points of nanostructures is that the intervals of matter excitation energies and the radiative corrections, which are both sensitive to the size and shape of matter, are comparable in magnitude. Thus the proper treatment of radiative shift is essential in obtaining correct results of optical responses. An example of the size dependence of (complex) eigenmode energies with the radiative shift $\text{Re}[\mathcal{E}]$ and width $\text{Im}[\mathcal{E}]$ is shown in Fig. 1 for an exciton weakly confined in a dielectric sphere. The large resonant variation at a certain size for each mode is due to the radiative correction $\mathcal{E}$, which shows the central importance of this quantity in the calculation of response spectrum.

In a macroscopic response theory, a resonance is ascribed to that of susceptibility, i.e., the resonance with a matter excitation energy. However, in the microscopic treatment, the resonance is ascribed to the resonant enhancement of internal electric field. Thus the self-consistent treatment of response is seen to lead to a rather different picture of resonance.

Cavity effect

Nonlocal scheme in terms of cavity green function

Induced polarization consists of various frequency components corresponding to the transitions among quantized levels of matter. For a given frequency of incident light, some of them are resonant and others are non-resonant. Since the number of transitions is infinite in general, it is not feasible to consider all the transitions in the above set of Eq. (9). To neglect all the non-resonant components is permissible only for optically thin systems, such as gases of atoms and molecules. For solids (and liquids, too),

Fig. 1 (i) Real and (ii) imaginary parts of the eigenmode energies of an exciton in a sphere with a background dielectric constant of $\epsilon_b = 5.6$. The material parameters correspond to those of the Z_3 exciton in CuCl. Each curve is specified by the total angular momentum J , its projection, the TE or TM mode character, and the radial quantum number for the exciton state.

however, we have to consider the effect of non-resonant (but infinitely many) components in dealing with the motions of resonant components. For appropriate configurations, these components produces “cavity modes” of EM field, which have completely different frequency spectrum and spatial structure from those of vacuum modes. The interaction of cavity modes and resonant matter transitions offers very interesting problems of cavity QED, remarkable enhancement effects and various typical situations showing the mechanism of light-matter interaction in a simplified manner.

A well-known recipe dealing with this kind of situation is to regard all the non-resonant components as an effective background medium of a given shape and size with electric susceptibility χ_b (background polarizability). Then, the Maxwell equation to determine electric field $E(r, \omega)$ is written as

$$\nabla \times \nabla \times E - q^2 \varepsilon_0 [1 + \chi_b \Theta(r)] E = q^2 P_{\text{res}} \quad (12)$$

where P_{res} is the resonant part of polarization. Defining the EM Green function $G_b(r, r'; \omega)$ of the background medium as

$$\nabla \times \nabla \times G_b - q^2 \varepsilon_0 [1 + \chi_b \Theta(r)] G_b = q^2 \delta(r - r'), \quad (13)$$

where $\Theta(r) = 1$ or 0 for r inside or outside the background medium, respectively, we can derive the solution of Eq. (12) as

$$E(r, \omega) = E_b(r, \omega) + \int dr' G_b(r, r'; \omega) \cdot P_{\text{res}}(r'; \omega),$$

where E_b is the field due to the background polarization alone. This field is equivalent to that of (4), expressed differently in terms of the Green function G_b .

In a nanostructure, resonant polarization of interest will consist of a few frequency components, and is written in the form of Eq. (8) with $\nu = 1, 2, \dots, s$. The equations to determine the X 's are Eq. (9) for $\nu = 1, 2, \dots, s$, but the parameters in the equations should be changed as follows. [A] The excitation energies $\{E_\nu - E_0\}$ contain the interaction energy of induced polarizations, which are affected by the presence of background dielectrics. This “screening” effect can be divided into bulk type and surface/interface type contributions. The former is the screened Coulomb interaction by the factor $1/\varepsilon_b$, where $\varepsilon_b = 1 + \chi_b$, and the latter is the image potential effect for the interaction among the components of induced charge density. [B] The evaluation of radiative interaction $\mathcal{A}$ should be made in terms of G_b instead of G . In terms of the modified excitation energies $\{E'_\nu - E_0\}$ and radiative correction $\mathcal{A}^{(b)}$, we solve Eq. (9) for $\nu = 1, 2, \dots, s$ to obtain the (modified) expansion coefficients X , which uniquely determine the response field and induced polarization.

A typical effect of cavity on the optical response of matter is the modification of mode structure of EM field and the characteristic spatial pattern of each mode. Through this change in EM field, the coupling with matter excitations can be strongly affected, and their resonant frequencies and widths are modified rather strongly. In optical response, there appear the resonant contribution of both cavity modes and matter excitations in general, where we can distinguish two regimes, namely, the case where cavity mode has much smaller Q-value than that of matter excitation and the case where their Q-values are comparable. In the former case, only the effect on the matter excitation is appreciable as an increase in its width, while, in the latter, there occur new coupled modes through the mixing of the cavity mode and matter excitation.

The two regimes mentioned above can be described by the single scheme of the microscopic response in a cavity. The condition for the existence of non-trivial solution of the modified equations for $\{X_{\nu 0}\}$ in the absence of external field leads to the eigenmodes of the matter in a cavity. The fact that this solution covers two different regimes can be seen from the structure of the eigenmode equation. The Green function G_b has poles at the energies of cavity modes, so that the radiative correction $\mathcal{A}$ has the same poles with the strength determined by the coupling with matter excitations. Thus, the eigenvalue equation

$$\det[(E'_\nu - E_0 - \hbar\omega) \mathbf{1} + \mathcal{A}^{(b)}] = 0 \quad (15)$$

provides the complex roots for the coupled cavity modes and matter excitations. Depending on the coupling strength in $\mathcal{A}^{(b)}$ and the imaginary parts of cavity modes contained in G_b , two regimes appear as mentioned in the previous paragraph.

EM Green function of cavity polariton

A typical example of matter in a cavity is a quantum well in a DBR (Distributed Bragg Reflector). In this case, the coupled modes are called cavity polaritons, and it is a very popular subject to study the nonlinear response of cavity polaritons, such as pump-probe spectroscopy, four wave mixing, parametric amplification, and so on. In these optical processes, probe beams are sent from outside the cavity, and the result of nonlinear process inside the cavity is observed as external light coming out of the cavity. A standard treatment of these processes is the so-called quasi-mode coupling scheme, where the cavity mode is assumed to be completely confined in the cavity, i.e., to have infinitely large Q-value. The well-defined cavity mode allows a simple and rigorous treatment of the light-matter coupling at various nonlinear levels, and the resulting signal light is calculated by assuming the coupling of ($Q = \infty$) cavity mode and the photon modes outside the cavity. The coupling strength is assumed to be such that it reproduces the radiative width of the cavity polaritons. This is used rather often, but it is a kind of make shift approach. This cannot be justified in a rigorous sense, because the problem of boundary conditions at the cavity surfaces cannot be translated into that of interaction between spatially separated modes of EM field.

An alternative way to handle such a problem rigorously is to use the Green function of cavity polariton, which is defined by renormalizing exciton linear polarization as well as background polarization comprising the cavity mode into the definition of EM

field causing the nonlinear optical interaction. The equation to define this Green function G_{cp} has a similar form as Eq. (13). The only difference is that it additionally contains on the left hand side a term representing the linear polarization due to exciton.

$$\nabla \times \nabla \times E - q^2 \varepsilon_0 [1 + \chi_b \Theta(r)] E + \varepsilon_0 \int d\mathbf{r}' \chi_x^{(1)}(\mathbf{r}, \mathbf{r}'; \omega) E(\mathbf{r}') = q^2 P_{NL} \quad (16)$$

Keeping the nonlocal character of $\chi_x^{(1)}$, one can solve this integro-differential equation, and obtain the analytical form of G_{cp} in terms of G_b alone. Since G_b is obtained in a simple form for a QW in a DBR cavity, G_{cp} can be used as a practical tool. Considering that G_{cp} describes the propagation of EM field both inside and outside the cavity according to the detailed construction of the cavity, we understand the merit of this Green function to calculate the signal field outside the cavity caused by the nonlinear interaction in the cavity.

The EM field produced by the nonlinear polarization is given as

$$E(\mathbf{r}, \omega) = E_{cp}(\mathbf{r}, \omega) + \int d\mathbf{r}' G_{cp}(\mathbf{r}, \mathbf{r}', \omega) \cdot P_{NL}(\mathbf{r}', \omega). \quad (17)$$

The main issue in this formalism is to give the explicit form of P_{NL} according to the problem in question. The nonlinear polarization contains several components of EM field, so that we need to require self-consistency conditions based on the above solution. It is noteworthy that the Green function for cavity polariton is obtained in a closed form through the use of nonlocal form of exciton linear polarizability. The use of local approximation for this polarizability leads to a Bethe-Salpeter type equation, which is much complicated to solve. Thus, the nonlocal description makes the solution much easier than the local one. This is another example to recommend the use of nonlocal way of description.

Examples of observed phenomena

The typical phenomena characterized by the microscopic description of the optical response remarkably emerge under the conditions beyond LWA scheme, where the spatial variation in the electric field becomes obvious. Thus, studying these phenomena under non-LWA conditions is helpful for understanding some essential elements of the optical response of nanostructures.

Nonlocality-enhanced electric quadrupole transition

At the resonance condition for X in Eq. (9) in the presence of an external field, induced polarizations are enhanced along with the internal field associated with the same spatial patterns of the polarizations. Because the nonlinear component of the polarization depends on the internal field, the signal intensity of the nonlinear response shows sensitive size and shape dependence under resonance conditions. This type of resonant enhancement has been observed for thin layered structures of high-quality GaAs crystals (Ishihara et al., 2002). In this experiment, the thickness dependence of four-wave mixing, which is a type of third-order nonlinear response, was studied, and a remarkable enhancement in the signal was observed for a particular thickness region around 100 nm (Fig. 2). The theoretical analysis based on microscopic nonlocal theory revealed that the enhanced response was caused by the polarization with a quadrupole-type spatial pattern that is optically forbidden under typical LWA conditions. This observation demonstrates the significant role of the microscopic nonlocality in the optical response of nanostructures.

In the macroscopic description based on the LWA, only the transition associated with the dipole-type polarization strongly contributes to the optical response. In reality, however, the nanoscale spatial structure of the field plays a significant role depending on the sample structure and the resonance condition; thus, the conventional selection rule does not necessarily hold true. The abovementioned observation in GaAs thin layers is a typical example. Such a breakdown also appears for single molecules when they couple with the highly localized electric field arising from elementary excitations such as surface plasmons. The collective oscillation of free electrons in metallic media is known as plasmons. In particular, in the presence of metallic nanostructures such as nanoscale gaps, the plasmons can be excited by incident light, and the associated electric field is a strongly localized and enhanced, which is called localized surface plasmon-polaritons. If the molecules interact with such strongly inhomogeneous electric field, optically forbidden transitions easily occur because the strong spatial structure of the field does not follow the selection rule of LWA regime. An experimental demonstration of this phenomenon has been reported for single-walled carbon nanotubes (SWCNTs) lying in nanogaps between gold nanoblocks (Takase et al., 2013). By using the resonant Raman scattering, an optically forbidden electronic transition for a single carbon nanotube has been observed, where the associated polarization has a quadrupole-type spatial pattern in the cross section of the SWCNT of approximately 1 nm in diameter. The theoretical verification has been made by nonlocal theory to properly treat the spatial relationship between the electric field and the induced polarizations in the SWCNT, which elucidates significant signal intensity from the optically forbidden transition (Fig. 3).

The scanning type of microscopy associated with photo-excitation is a promising technique to observe the optically forbidden transitions of single nanostructures. Among such techniques, photo-induced force microscopy (PiFM) is considered a powerful method (Rajapaksa et al., 2010). PiFM uses a probe of atomic force microscopy (AFM) coated with a metal and detects the photo-induced force between the sample and the probe tip irradiated with light. The electric field in the vicinity of the sample and the probe is strongly enhanced by the localized surface plasmon resonance, and the induced force is strengthened. As this method

(b) The thickness (X in the picture of (a)) dependence of the peak value of the DFWM intensity. Closed circles are measured values in arbitrary units. The solid line shows the calculated values normalized by the incident probe intensity. The assumed damping constant is 0.03 meV. Modified after Ishihara H, Cho K, Akiyama K, Tomita N, Nomura Y and Isu T (2002) Large four-wave mixing of spatially extended excitonic states in thin gaas layers. *Physical Review Letters* **89**(1): 017402.

Fig. 3 Cross-sectional view of the calculated intensity of the electric field under resonant excitation conditions of the exciton with quadrupole-type polarization of an SWCNT lying between gold nanoblocks. The calculated quadrupole polarization is indicated by the black arrows. The grids show the cell size in the calculation by the discrete dipole approximation (DDA). The inset shows the overall view of the gold nanoblocks and SWCNT. Modified after Takase M, Ajiki H, Mizumoto Y, Komeda K, Nara M, Nabika H, Yasuda S, Ishihara H and Murakoshi K (2013) Selection-rule breakdown in plasmon-induced electronic excitation of an isolated single-walled carbon nanotube. *Nature Photonics* **7**(7): 550–554.

does not require the detection of the scattered or propagated fields, it possesses a high potential of molecular scale resolution. Recently, a scheme of high-resolution PiFM has been developed based on the heterodyne frequency modulation method in an ultrahigh vacuum (Yamanishi et al., 2017) to remove the photothermal oscillations. Presuming the potential of this technique, the observation of the spatial polarization patterns of the optical forbidden transitions in the nanostructures have been theoretically demonstrated (Yamane et al., 2020), as shown in Fig. 4. This effect can be considered a typical example to observe the non-LWA aspect of the optical response in nanostructures.

Fig. 4 (a) Schematic of the PiFM model. The metal-coated tip is modeled as a gold sphere. (b) Schematic illustration of the dimer on the gold substrate with the tip position. The grid on the substrate represents the cells in the DDA calculation. The center of the tip is represented by the white dots. (c) Photo-induced force spectra. The lines represent the dimer states, and each tip position in (b) is shown. As the tip moves away from the dimer, the peak corresponding to the allowed anti-bonding (AA) state becomes smaller, whereas the peaks corresponding to the allowed bonding (AB) and the forbidden bonding (FB) states appear strongly in the range of 2.8–4.2 nm. Also, the forbidden anti-bonding (FA) state appears in the same range. (d), (e), and (f) depict the PiFM images of the dimer for the AA, FB, and AB states, respectively (For the polarization patterns of AA, FB, and AB, see, insets of (d), (e) and (f), respectively.). The PiFM images are normalized by the force when the tip is just on the substrate (F_0). The dimer is represented by the green squares. Modified after Yamane H, Yamanishi J, Yokoshi N, Sugawara Y and Ishihara H (2020) Theoretical analysis of optically selective imaging in photoinduced force microscopy. *Optics Express* **28**(23): 34787–34803.

Radiative correction of nondipole-type excited states

As explained in Section “Scheme of microscopic response”, $\det |\mathbf{S}| = 0$ provides the complex eigenenergies $\{\hbar\Omega_\lambda\}$ of the coupled light-matter system. Generally, $\hbar\Omega_\lambda$ includes the radiative correction, namely, the real part of $\hbar\Omega_\lambda$ corresponds to the eigenenergy of the λ state including the shift from the original bare excited level, and the imaginary part corresponds to its radiative decay rate. One of characteristic phenomena that microscopic response theory predicts is the large radiative correction of nondipole-type excited states appearing beyond the LWA regime. If the wavefunctions of dipole-type excited states coherently extend over the entire volume of the sample within the LWA regime, the light-matter interaction volume and the radiative correction are proportional to the sample volume. However, if the sample size becomes comparable to the wavelength of the external light in a medium, this size-linear enhancement is saturated owing to the spatial variation in the light field in reality. On the other hand, beyond the LWA regime, the higher-order (nondipole-type) states strongly couple with light if the sample size allows the phase of their polarization waves to match the light wave in a medium. Thus, the light-matter interaction volume itself is not limited by the light wavelength, and the higher-order states (including the optically forbidden one in the LWA) attain maximum coupling at a particular size one after the other, leading to a large light-matter interaction volume. This situation was theoretically predicted, as seen in Fig. 1.

Because the respective components of polarization $X_{\nu 0}$ are resonantly enhanced at $\text{Re}[\hbar\Omega_\lambda]$ in the presence of the external field, a corresponding radiative shift can be observed in the spectra of the light scattering, photoluminescence, and so on. As an example, in Ref. Syouji et al. (2004), nondegenerate two-photon excitation scattering was employed to observe light-matter coupled modes, where both of the incident two beams are far from resonance with the one-photon excitation energy. (It should be noted that the resonance structures of $X_{\nu 0}$ do not correctly appear in the one-photon spectrum such as the reflectance or transmittance because of the interference between the scattered light and the external light.) When the sum energy of the photons from the two lasers resonates with the excitation energy of the light-matter coupled state, $\hbar\Omega_\lambda$, resonant scattering occurs. This experiment was done by using CuCl thin films and validated the characteristic size dependence of the radiative shift predicted in Fig. 1, where the shift drastically decreases and increases depending on the phase relation between the induced polarization and the light. In Ref. Syouji et al. (2004), a level interchange due to a large radiative shift was demonstrated, where the lowest state in the original bare level scheme overtakes the upper levels one by one as the thickness increases. In other nonlinear spectroscopy, four-wave mixing is also an effective method to observe the light-matter coupled states. Information about $\{\hbar\Omega_\lambda\}$ can be clearly obtained because the spectrum reflects $\text{Re}[X_\lambda]$ well (Fig. 5) (Ichimiya et al., 2009). The luminescence spectra also directly reflect the light-matter coupled levels (Phuong et al., 2012). Typically, luminescence occurs from the excited states around the lowest one after reaching quasi-equilibrium. However, the spectra observed in Phuong et al. (2012) are different from the usual ones; the peak structures corresponding to the light-matter coupled states clearly appear, even for higher-order states with non-dipole type polarization patterns because those excited states emit light before their dephasing process owing to their large radiative decay rate, as explained below.

Fig. 5 (a) Gray lines: Calculated eigenenergies of bare excitons confined in a CuCl thin film. Black lines: Calculated real parts of the eigenenergies of the light-exciton coupled mode. (b) Calculated imaginary parts (radiative widths) of the eigenenergies of the light-exciton coupled mode. (c) Observed spectrum of the DFWM intensity. Vertical lines show the eigenenergies of the light-exciton coupled mode for the 187-nm-thick film.

Fig. 6 (a) Schematic illustration of the double component excitons in ZnO. (b) Schematics of the radiative coupling of the A and B excitons. The bright modes formed by the multipoles of A and B excitons show a cooperative emission that becomes faster than the thermal dephasing at room temperature. (c) Experimentally observed fast radiative decay in the order of 10 fs. The solid red lines represent the fitting curves by a double-exponential function convoluted using the excitation laser profile. Modified after Kinoshita T, Matsuda T, Takahashi T, Ichimiya M, Ashida M, Furukawa Y, Nakayama M and Ishihara H (2019) Synergetic enhancement of light-matter interaction by nonlocality and band degeneracy in ZnO thin films. *Physical Review Letters* **122**(15): 157401.

Ultrafast radiative decay overcoming thermal dephasing at room temperature

Another characteristic manifestation of enhanced light-matter coupling beyond the LWA regime is ultrafast radiative decay reflecting the large $\text{Im}[\hbar\Omega_c]$. As explained above, the radiative correction is proportional to the sample volume in the LWA regime; therefore, the radiative decay rate exhibits a size-linear enhancement. This effect is known as “one-photon super radiance (giant oscillator strength).” On the other hand, beyond the LWA regime, the radiative decay rate exhibits a different type of size dependence, which is not simply the size-linear type but that overlapped with resonance behavior (as seen in Fig. 1), and exceptionally fast radiative decay occurs. This type of super radiance has been demonstrated in Ref. [Phuong et al. \(2012\)](#) for a CuCl thin film with a thickness of a few of hundred nanometers, where some modes exhibited radiative decay within approximately 100 fs. If we aim for further optimized conditions, we can realize significantly faster radiative decay reaching an order of 10 fs decay time. Such a decay time is shorter than the typical dephasing time of the excited states of solids at room temperature ([Becker et al., 1988](#)). Thus, in this scenario, the photoluminescence is completed before the thermal disturbance occurs, namely, a thermal-free optical response would be possible. A similar type of fast radiative decay has been observed in experiments for ZnO thin films ([Kinoshita et al., 2019](#)). The ZnO excitons have a multi-component nature arising from the nearly degenerate valence bands. The excitons related to the transitions from the topmost and the second valence bands are labeled A and B excitons, respectively. Because of the synergetic enhancement of the light-matter interaction due to these two exciton branches, the radiative decay time becomes shorter than a couple of tens of fs as observed by the transient grating spectroscopy, as depicted in Fig. 6.

Finally, it is useful to address how the super radiance regime is logically connected with the radiative decay scheme for the bulk regime. It is known that the radiative decay rate of light-matter coupled states (polaritons) in the bulk regime is inversely proportional to the sample size, which is opposite to that for the super radiance regime because the decay in the bulk regime is described as the escape of polariton wavepackets from the sample surfaces. In the super radiance regime, the apparent propagation speed v_p of the light-matter coupled mode with the strongest coupling for each thickness can be defined (see Ref. [Bamba and Ishihara, 2009](#) for details). At the crossover size between the super radiance regime and the bulk regime, v_p reaches the group velocity $c/2n_{bg}$ of a polariton, where n_{bg} is the refractive index of the background medium. Then, beyond this condition, the photon created by electron-hole recombination cannot go outside of the film without reabsorption when its propagation speed is beyond the group velocity. This explains how we can understand the crossover between the size regimes described with the super radiance scheme and that described with the polariton scheme. This crossover behavior has been experimentally observed by Takahata et al. through the absorption measurement of carefully prepared Cu₂O tapered thin films ([Takahata et al., 2018](#)). Around the resonance regions of the blue and violet excitons, the systematic thickness dependence of the eigenenergies of the radiatively coupled excitons is investigated and the crossover from the super radiance and the polariton regimes is confirmed.

Conclusion

One characteristic aspect of the optical response of nanostructures is the explicit dependence on the size, shape, and internal structure of matter. These characteristics arise owing to the confined excited states whose eigen energies are quantized and the wave functions demonstrate various spatial structures depending on the boundary conditions. The optical response of nanostructures is also strongly modified by the dielectric structures of the background and/or environmental medium. This chapter has discussed the scheme to address these features with a single theoretical framework and illustrated some typical examples of phenomena observed in various experiments.

The nonlocal response is the key concept to providing a good overview of the optical response of nanostructures based on the first-principles formulation of light-matter interaction. To address the microscopic nonlocal response, we describe the susceptibility as a function of two positions using the system's wave functions extended coherently over the entire sample. By coupling the constitutive equations described with the non-local susceptibility and the microscopic Maxwell equation, the self-consistent optical response can be obtained. Solutions include radiative correction (energy shift and width corresponding to the inverse of the lifetime). The radiative width is a more generalized measure of the strength of the light-matter interaction than the oscillator strength that has been used conventionally under the long-wavelength approximation. This framework can be applied not only to the linear response but also to the nonlinear response by providing nonlinear susceptibility.

The strong modification of the mode of the EM field owing to the spatial dielectric structures of the background and/or environmental medium can be reflected through the EM Green function in the Maxwell equation. The cavity effect from the low-Q to the high-Q cases can be treated by this method. Depending on the Q-value, the mode structure of the EM field and the characteristic spatial pattern of each mode are modified. Through this change in the EM field, the coupling with matter excitations can be strongly affected, and their resonant frequencies and widths are strongly modified.

The effects characterized by the nonlocal response, namely the effects where the interplay between the spatial structures of matter wave functions and those of EM fields plays an essential role, have been observed in various experiments. Typical examples are the large nonlinear response of the electric quadrupole transition of semiconductor thin films, and the Raman scattering by the resonant excitation of the optically forbidden states of single-walled carbon nanotubes lying near metallic nanogaps sustaining localized surface plasmons. Another remarkable manifestation of the non-local response is the ultrafast response at a single fs level caused by the exciton-light coupling beyond the LWA scheme.

As demonstrated in experiments, the microscopic nonlocal theory is not only significant for rigorous descriptions of nanostructure optical responses but also crucial for revealing unconventional optical effects beyond the dipole approximation of matter systems and long-wavelength approximations of the field. Namely, paying attention to the full spatial degrees of freedom of the EM field and the matter wave functions in nanostructures paves a new avenue for exploring the potential of nanostructures as functional materials and for designing novel devices.

Abstract

In this chapter we review basic features of semiconductors and dielectrics from the perspective of optical and infrared properties. We consider Maxwell's macroscopic equations and the propagation of electromagnetic waves in solids. The constitutive material relation is described by the dielectric tensor which is a function of light frequency and may also depend on the external or internal parameters leading to birefringence, magneto- and electro-optical effects, piezospectroscopy and the spatial dispersion, e.g., natural optical activity. The linear optics is focused on the light reflection, transmission and absorption as the standard methods of noninvasive characterization of materials. An important attention is attracted to the excitonic effects in semiconductors, semiconductor structures and molecular crystals, as well as to the fine structure of exciton levels. Mixing of a photon and a quasi-particle excitation is shown to result in formation of hybrid excitations, polaritons. We outline the well-established optical materials such as dielectrics activated by impurities and novel solids such as

metamaterials, resonant microcavities and photonic crystals. The chapter also touches upon the polarized photoluminescence spectroscopy. The nonlinear optics is represented by second harmonic generation and pump-probe spectroscopy. Novel trends are illustrated by single-photon sources and two-photon entanglement.

Key points

The basic optical properties of semiconductors and dielectrics are the main theme of this chapter.

- Maxwell's macroscopic equations and the propagation of electromagnetic waves in solids
- Dielectric tensor, complex dielectric function
- Light reflection and transmission
- Light absorption, direct and indirect transitions
- The tensor nature of the permittivity
- Coulomb interaction effects, excitons, fine structure of exciton levels, Sommerfeld factor
- Phonon and exciton polaritons
- Quantum microcavities, metamaterials, photonic crystals
- Polarized photoluminescence, optical orientation of electron spins, magnetic circular polarization of photoluminescence
- Color centers, laser materials
- Single-photon sources, two-photon entanglement
- Nonlinear optics, second harmonic generation, pump-probe spectroscopy, spin Faraday and Kerr rotation

Introduction

The chapter addresses basic features of semiconductors and dielectrics from the perspective of optical and infrared properties. These solids differ from metals by existence of the electron band gap E_g . Without doping and defects and at low temperature they have absolutely empty conduction bands above completely filled valence bands and are insulators contradistinguished from metals by their vanishing direct-current conductivity at low temperature. In most textbooks, the insulating/metallic behavior is explained by means of the band structure theory, focusing on the position of the Fermi level of the given material: either in a bandgap (dielectrics and semiconductors), or within a band (metals).

The dielectrics are characterized by wide band gaps and narrow allowed electron bands, whereas wide allowed and narrow forbidden bands are typical for semiconductors. Strictly speaking, there is no well-defined division between these substances, but nevertheless, for most cases, it is possible. The examples of typical semiconductors are Ge, Si, Te, GaAs and other A_3B_5 compounds, CdTe and other A_2B_6 compounds, MoS_2 and other transition metal dichalcogenides. The well-known examples of dielectrics include quartz, corundum (Al_2O_3), BN ($E_g \approx 6$ eV), NaCl ($E_g \approx 9$ eV), EuF_2 , anthracene, solid C_{60} (fullerite).

Optical spectroscopy suggests noninvasive studies of solid state materials, bulk crystals and disordered solids as well as low-dimensional structures. Various optical spectroscopic techniques provide investigation of light reflection, transmission, absorption, luminescence, light scattering, nonlinear optics. Each of these fields examines the different mechanisms of the light-matter interaction. In particular, the field of light scattering includes elastic, or Rayleigh, and inelastic (free-carrier, Brillouin and Raman) scattering processes. In its turn the Raman scattering can involve participation of optical phonons, plasmons, spin-flip and intersubband electronic excitations, surface or interface vibrations etc. The nonlinear optics comprises nonlinear absorption (e.g., the two-photon absorption), four-wave mixing, optical harmonic generation etc. The study of photocurrent generation, a nonlinear effect of the second order, reveals combined optical and transport properties. A full review of all these phenomena lies beyond the present chapter. Here we mostly focus on the linear optical phenomena, light propagation, reflection, absorption and luminescence. An outlook to some light-scattering and nonlinear optical issues is given in this chapter as well.

It should be noted that Guizzetti and Patrini (2023) and the present chapter provide two levels of presentation. In the former, the optical properties are described, basing mostly on classical arguments, for homogeneous, isotropic and non-magnetic materials. The latter presents a more in-depth description and needs the knowledge of quantum mechanics and band theory of solids.

Electromagnetic waves in solids

The propagation of electromagnetic waves in solids is described by Maxwell's macroscopic equations

$$\begin{aligned} \text{curl } \mathbf{H} &= \frac{\partial \mathbf{D}}{\partial t}, \quad \text{curl } \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \\ \text{div } \mathbf{D} &= 0, \quad \text{div } \mathbf{B} = 0, \end{aligned} \quad (1)$$

which relate four fields: the electric field vector E , the electric displacement D , the magnetic field strength H and the magnetic induction field, or the magnetic flux density, B . In order to apply the Maxwell's equations, it is necessary to specify two additional relations between these fields. In SI, the electric permittivity and magnetic permeability in vacuum are fundamental physical constants: $\mu_0 = 4\pi \times 10^{-7} \text{ Hm}^{-1}$, $\epsilon_0 = (\mu_0 c^2)^{-1}$, where c is the speed of light in vacuum. Here we mostly use the form of constitutive relations where the magnetic induction B coincides with $\mu_0 H$ and the electric field E and the electric displacement D are connected by the dielectric tensor. This form of the material equations is possible as soon as the electromagnetic field frequency is nonzero. However, in Section "Metamaterials" while discussing the directional energy flux of an electromagnetic wave (Poynting vector) we use a more general description.

An electric field of the plane monochromatic light wave propagating in a homogeneous medium is a linear combination of the complex conjugate exponential functions

$$E(t, \mathbf{r}) = E(\omega, \mathbf{q})e^{-i\omega t + i\mathbf{q}\mathbf{r}} + E^*(\omega, \mathbf{q})e^{i\omega t - i\mathbf{q}\mathbf{r}},$$

where ω and $\mathbf{q}$ are the light frequency and wave vector, $E(\omega, \mathbf{q})$ is the complex electric field amplitude. For the plane waves, the material equation reads

$$D_\alpha(\omega, \mathbf{q}) = \epsilon_{\alpha\beta}(\omega, \mathbf{q})E_\beta(\omega, \mathbf{q}), \quad (2)$$

where $\epsilon_{\alpha\beta}$ is the relative permittivity tensor or the dielectric tensor. The Onsager symmetry relations impose the following constraint on the dielectric tensor

$$\epsilon_{\alpha\beta}(\omega, \mathbf{q}) = \epsilon_{\beta\alpha}(\omega, -\mathbf{q}). \quad (3)$$

It should be noted that the macroscopic description of fields in solids is valid as soon as the light wavelength $\lambda = 2\pi/q$ exceeds the microscopic dimension of the crystal unit cell. In the transparency frequency region, i.e., in the absence of absorption, the dielectric tensor is a Hermitian matrix, $\epsilon_{\alpha\beta}(\omega, \mathbf{q}) = \epsilon_{\beta\alpha}^*(\omega, \mathbf{q})$. The frequency dependence of $\epsilon_{\alpha\beta}$ means that the displacement $D(t)$ is determined by the electric field $E(t')$ not only at the same time $t' = t$ but also at previous instances $t' < t$. In the same way, the $\mathbf{q}$ -dependence of the dielectric tensor, or the spatial dispersion, implies a nonlocal response in real space, such that $D(t, \mathbf{r})$ depends on $E(t', \mathbf{r}')$ in some region around the point $\mathbf{r}$.

The dielectric tensor may also depend on the external or internal parameters, namely, the strain tensor components u_{ij} , the static electric field $E^{(0)}$ or magnetic field $B^{(0)}$, the static magnetization $\mathbf{M}$ etc. Consequently, in this case the transposition in Eq. (3) should be accompanied by the time inversion T of these parameters, $Tu_{ij} = u_{ij}$, $TE^{(0)} = E^{(0)}$, $TB^{(0)} = -B^{(0)}$, $TM = -M$ in the argument of the dielectric tensor.

It is worth mentioning that sometimes, instead of the dielectric tensor, one uses the electric susceptibility χ which connects the induced electric polarization density of the medium $\mathbf{P}$ with the electric field $\mathbf{E}$

$$\mathbf{P}_\alpha = \epsilon_0 \chi_{\alpha\beta} \mathbf{E}_\beta. \quad (4)$$

The two tensors are connected by $\epsilon_{\alpha\beta} = \epsilon_0(\delta_{\alpha\beta} + \chi_{\alpha\beta})$. Note also that, on some occasions, the introduction of the optical conductivity tensor $\sigma_{\alpha\beta}(\omega) = -i\omega\epsilon_0[\epsilon_{\alpha\beta}(\omega) - \delta_{\alpha\beta}]$, instead of $\epsilon_{\alpha\beta}$, makes more sense. This tensor relates the electric current density $\mathbf{j} = -i\omega\mathbf{P}$ with the vector $\mathbf{E}$

$$\mathbf{j}_\alpha = \sigma_{\alpha\beta} \mathbf{E}_\beta. \quad (5)$$

In crystals of cubic symmetry and in the absence of the spatial dispersion the dielectric tensor is isotropic and reduces to a scalar dielectric function $\epsilon(\omega)$.

Complex dielectric function

The dielectric function $\epsilon(\omega)$ is a complex function of the real frequency ω . Its real and imaginary parts, ϵ' and ϵ'' , obey the Kramers–Kronig relationship

$$\begin{aligned} \epsilon'(\omega) - 1 &= \frac{1}{\pi} \mathcal{P} \int_{-\infty}^{\infty} \frac{\epsilon''(\Omega)}{\Omega - \omega} d\Omega, \\ \epsilon''(\omega) &= -\frac{1}{\pi} \mathcal{P} \int_{-\infty}^{\infty} \frac{\epsilon'(\Omega) - 1}{\Omega - \omega} d\Omega, \end{aligned} \quad (6)$$

where $\mathcal{P}$ denotes the Cauchy principal value.

In a solid with the dielectric function $\epsilon(\omega)$, the dispersion equation relating $\mathbf{q}$ with ω has the form

$$\left(\frac{cq}{\omega}\right)^2 = \epsilon(\omega) \quad (7)$$

and, therefore, the wave vector is given as $q(\omega) = (\omega/c)\bar{n}(\omega)$. Here we introduced the complex index of refraction

$$\bar{n} = \sqrt{\varepsilon} = n + i\kappa.$$

The parameters n and κ are called the refractive index and extinction coefficient, respectively. The equations relating real and imaginary parts of ε and $\bar{n}$ are $\varepsilon' = n^2 - \kappa^2$ and $\varepsilon'' = 2n\kappa$.

A plane light wave propagating in the homogeneous media with the extinction coefficient κ exhibits the attenuation. The Beer–Lambert–Bouguer law relates the attenuation of light intensity $I \propto |E(\omega, z)|^2$ to the extinction coefficient of the bulk material through which the light is traveling along the z axis: $I(z) = I(0)e^{-\alpha z}$, where the absorption coefficient $\alpha = 2\omega\kappa/c = \omega\varepsilon''/cn$.

Optical reflection and transmission

Let a plane electromagnetic wave be incident on a plane boundary between two solids with the complex refractive indices $\bar{n}_1$ and $\bar{n}_2$. The amplitude reflection and transmission coefficients, r and t respectively, are described by the Fresnel equations. At normal incidence from the medium 1 into the medium 2 they read

$$r = \frac{\bar{n}_1 - \bar{n}_2}{\bar{n}_1 + \bar{n}_2}, \quad t = \frac{2\bar{n}_1}{\bar{n}_1 + \bar{n}_2}. \quad (8)$$

For real $\bar{n}_{1,2}$ the light wave exhibits a phase shift of 180° when the reflectance takes place in a medium of lower refractive index than the adjoining medium, and zero if $n_1 > n_2$. The reflectance R (the intensities ratio) is the squared absolute value of r .

The reflection under oblique incidence from vacuum to the material with the refractive index $\bar{n}$ is characterized by the complex amplitude reflection coefficients

$$\begin{aligned} r_s &= \frac{\cos \theta_t - \bar{n} \cos \theta_i}{\cos \theta_t + \bar{n} \cos \theta_i}, \\ r_p &= -\frac{\cos \theta_i - \bar{n} \cos \theta_t}{\cos \theta_i + \bar{n} \cos \theta_t}, \end{aligned} \quad (9)$$

where the indices s and p indicate the light polarization, respectively perpendicular and parallel to the plane of incidence, θ_i is the incidence angle (real) and the refractive angle is defined by $\theta_t = \sqrt{1 - \sin^2 \theta_i / \bar{n}^2}$. The negative sign in the second Eq. (9) is due to the choice of the direction of the p -polarized reflected light. If the medium of refraction is transparent, $\bar{n} = n$, the refractive angle θ_t is real and connected with θ_i by the Snell's law $\sin \theta_t = n \sin \theta_i$. In this case the reflectivity of p -polarized light vanishes at Brewster's angle $\theta_{Br} = \arctan n$.

The spectroscopic ellipsometry technique allows to measure the ratio $\rho = r_p/r_s$ known as the ellipsometric function and presented in the form $\rho = e^{i\Delta} \tan \Psi$, where $\tan \Psi$ is the amplitude ratio and Δ is the phase shift upon reflection. For real values of ε the phase shift takes two values $\Delta = 0$ and 180° .

Thin films

Let us consider a thin film coated on a thick substrate. Then the light components reflected at the top and bottom surfaces of the film interfere with each other. In general, the phase shift ϕ between the two components can take any value. The special cases are $\phi = 2N\pi$ and $\phi = (2N + 1)\pi$, where N is an integer. In the former case it is said that the beams interfere constructively and in the latter destructively. By adjusting the film parameters one can achieve the antireflection which is more or less complete cancellation of the reflected components.

An opposite effect of a high reflectance can be obtained from a distributed Bragg reflector which is a stack of thin quarter-wave dielectric layers of alternate high and low indices n_1 and n_2 . The layer thicknesses a_1, a_2 satisfy the conditions

$$n_1 \frac{\bar{\omega}}{c} a_1 = n_2 \frac{\bar{\omega}}{c} a_2 = \frac{\pi}{2},$$

where $\bar{\omega}$ is the frequency chosen to be in the center of the enhanced reflection spectral region.

Optical absorption

The absorption spectrum spans a wide energy range extending from the above- or near-bandgap energies to the low energy transitions involving free carriers and optical phonons.

Interband absorption

The simplest form of absorption may be a direct transition from the valence to the conduction band. The optical excitation of one electron from the valence band v to the conduction band c leads to a generation of an extra electron with the wave vector k_c in the

conduction band, leaving an empty state with the wave vector $\mathbf{k}_v$ in the valence band. The vertical transitions between the electronic bands v and c occur for $\mathbf{k}_c = \mathbf{k}_v = \mathbf{k}$ and obey the energy conservation law

$$\varepsilon_{ck} - \varepsilon_{vk} = \hbar\omega,$$

where $\hbar\omega$ is the excitation photon energy.

For the direct optical transitions one has

$$\varepsilon'' = \frac{cn}{\omega} \alpha = \frac{4\pi^2 e^2}{\omega^2 V} \sum_{n'nk} |\mathbf{e} \mathbf{v}_{n'n}(\mathbf{k})|^2 (f_{n'k} - f_{nk}) \delta(\varepsilon_{n'k} - \varepsilon_{nk} - \hbar\omega), \quad (10)$$

where V is the sample volume, e is the electron charge, the indices n' , n enumerate the electron bands, $\mathbf{v}_{n'n}(\mathbf{k})$ is the matrix element of the velocity operator between the Bloch states n' , $\mathbf{k}$ and n , $\mathbf{k}$, ε_{nk} is the electron energy dispersion in the n -th band, and f_{nk} is the electron distribution function. For the allowed band-to-band transitions $v \rightarrow c$ in direct-gap semiconductors Eq. (10) may be written down as

$$\varepsilon'' = C \left(\frac{ep_{cv}}{\hbar\omega m_0} \right)^2 \sqrt{\mu_{cv}^3 (\hbar\omega - E_g)}, \quad (11)$$

where C is the dimensionless coefficient and m_0 is the electron mass in vacuum, p_{cv} is the interband matrix element of the momentum operator, μ_{cv} is the electron-hole reduced effective mass. Clearly, the absorption coefficient follows the interband density of states.

In indirect-gap semiconductors, the energy maximum in the valence and minimum in the conduction band do not occur at the same wave vector. In this case near-bandgap absorption takes place due to the indirect optical transitions provided by simultaneous scattering by phonons or static defects. For the non-phonon indirect transitions the absorption coefficient increases with frequency as the square of the energy difference $\hbar\omega - E_g$. For indirect transitions with the participation of lattice phonons the momentum conservation law reads $\mathbf{k}_c = \mathbf{k}_v \pm \mathbf{k}_{\text{phon}}$, and the absorption coefficient is proportional to $(\hbar\omega - E_g \pm \hbar\omega_{\text{phon}})^2$, where $\mathbf{k}_{\text{phon}}$, ω_{phon} are the phonon wave vector and frequency, the sign $\pm$ corresponds to the absorption and emission of the phonon. Fig. 1 presents the electronic indirect band structure in bulk MoS₂ and direct band structure in monolayer MoS₂ (Yazyev and Kis, 2015).

The absorption far below E_g can arise due to the transitions involving free carriers, defects, donors or acceptors or deep centers, as well as phonons. It can also be related to surface energy states within the band gap. This is particularly the case in topological insulators. A topological insulator is an electronic material that has a band gap in its interior like an ordinary insulator but possesses conducting states on its edge or surface. In the topological band theory, the role of the Gaussian curvature and the Euler characteristic of a topological space is played by the Berry curvature and the Z_2 topological invariant. Two insulators are equivalent if they can be transformed one into the other by slowly changing the Hamiltonian without gap closure, their topological invariants coincide. Let us consider a spatial interface between two insulators with different topological invariants (two materials or a material neighboring vacuum). Somewhere along the normal to the interface the energy gap has to vanish, because otherwise the two phases would be equivalent. The gapless states are surface states (or edge states in two-dimensional systems) that are topologically protected and exhibit conducting properties. The light absorption appears due to optical transitions between the surface states and between the surface and bulk states of the conduction or valence bands.

Intraband absorption

Considering free-carrier intraband absorption in the Drude model, we can start from the classical equation for a free motion of conduction electrons in the ac electric field of the electromagnetic wave

$$\dot{\mathbf{v}}(t) + \frac{\mathbf{v}(t)}{\tau_p} = \frac{e}{m^*} \mathbf{E}(t), \quad (12)$$

where $\mathbf{v}$ is the mean electron velocity, m^* and τ_p are the electron effective mass and the momentum relaxation time. The amplitudes of the electric current density and the electric field are related by

$$\mathbf{j}(\omega) = eN\mathbf{v}(\omega) = \sigma(\omega)\mathbf{E}(\omega),$$

where $\sigma(\omega) = \sigma(0)/(1 - i\omega\tau_p)$ is the ac conductivity (or the contribution of free carriers to the optical conductivity), $\sigma(0) = e^2 N \tau_p / m^*$ is the dc conductivity and N is the electron density. The absorption coefficient is given by

$$\alpha = \frac{4\pi}{cn} \text{Re} \{ \sigma(\omega) \} = \frac{4\pi\sigma(0)}{cn(1 + \omega^2\tau_p^2)}. \quad (13)$$

The tensor nature of the permittivity

The tensorial character of the permittivity is manifest in anisotropic structures or in crystals of cubic symmetry if they are subjected to external forces or the spatial dispersion is taken into consideration.

Fig. 1 Schematics of indirect- and direct-gap electron band structure of transition metal dichalcogenides (TMDC). (a) Bulk material. The valence band top, red circle, lies at the center of the Brillouin zone (Γ point) and conduction band bottom, blue circle, is located between Γ and K points. (b) TMDC monolayer. The valence band maximum and conduction band minimum lie at the same point K (vortex of the hexagon Brillouin zone). Birefringence

Anisotropic crystals are very different from the isotropic media: in an anisotropic medium a refractive index depends on the polarization and propagation direction of light. First, we consider non-magnetic crystals unaffected by external forces and ignore the spatial dispersion. Then the dielectric tensor $\varepsilon_{\alpha\beta}(\omega)$ is symmetric and, therefore, there is a Cartesian coordinate frame with the axes 1, 2, 3 where this tensor becomes diagonal with the components ε_{11} , ε_{22} and ε_{33} . If all three components are different, the crystal is called biaxial.

In a uniaxial material the two principal components coincide, e.g. $\varepsilon_{11} = \varepsilon_{22} = \varepsilon_{\perp}$, and differ from the third component $\varepsilon_{33} \equiv \varepsilon_{\parallel}$. The two fundamental light waves propagating in a particular direction are linearly polarized and have, except for $\mathbf{q} \parallel 3$, different refractive indices. One of them, called ordinary or transverse-electric (TE), is polarized perpendicularly to the optical axis (the axis 3) and the vector $\mathbf{q}$ and governed by the refractive index $\bar{n}_o = \sqrt{\varepsilon_{\perp}}$. The electric field in the other mode, extraordinary or transverse-magnetic (TM), is polarized in the plane formed by the wave vector and optical axis. For the light propagating in any direction perpendicular to the optical axis, the refractive index of the extraordinary wave $\bar{n}_e$ equals $\sqrt{\varepsilon_{\parallel}}$. If at the initial point the electric field vector of the light makes 45° with the optical axis, its polarization oscillates as a function of the propagation coordinate

changing from linear to circular at the quarter-wave distance and to orthogonal linear at the half-wave distance. Birefringent materials, e.g. quartz SiO_2 , calcite CaCO_3 or even plastics, are used to construct quarter- and half-wave plates, the former converts the linear polarization into circular polarization and the latter rotates the linear polarization direction by 90° .

Magneto- and electro-optical effects

Confining ourselves to the second-order magneto-optic effects, the dielectric tensor can be expanded in the components of the external static magnetic field $\mathbf{B}^{(0)}$

$$\varepsilon_{\alpha\beta}(\omega, \mathbf{B}^{(0)}) = \varepsilon_{\alpha\beta} + f_{\alpha\beta} B_{\eta}^{(0)} + Q_{\alpha\beta\eta\xi} B_{\eta}^{(0)} B_{\xi}^{(0)}. \quad (14)$$

It follows from the Onsager relation that, in non-magnetic media invariant under time reversal, the tensor f is antisymmetric and the tensor Q is symmetric with respect to permutation of the indices α and β .

The tensor f describes the Faraday effect of the optical rotation produced in a beam of linearly polarized light traversing a medium along the lines of force of an external magnetic field. This tensor also describes the circular dichroism and magneto-optical Kerr effect observed in reflection. The tensor Q describes the Voigt effect (or Cotton-Mouton effect) and contributes to a magnetic-field induced birefringence which can be observed when the light propagates perpendicularly to the applied magnetic field.

The expansion of the dielectric tensor in powers of the magnetic field is valid in the optical regions far enough from the exciton resonances. Otherwise, one has to take into account the excitonic effects and terms of higher order in $\mathbf{B}^{(0)}$ in Eq. (14) become important.

In ferromagnets and antiferromagnets, it is reasonable to reveal the role of the magnetic subsystems and express a change in $\varepsilon_{\alpha\beta}$ as a function of the internal parameters of the magnetic ordering. In a two-sublattice antiferromagnet one can write down

$$\begin{aligned} \varepsilon_{\alpha\beta}^a(\omega, \mathbf{L}, \mathbf{M}) &= f_{\alpha\beta\nu}^L L_\nu + f_{\alpha\beta\nu}^M M_\nu, \\ \varepsilon_{\alpha\beta}^s(\omega, \mathbf{L}, \mathbf{M}) &= \varepsilon_{\alpha\beta}(\omega) + Q_{\alpha\beta\nu\xi}^{LL} L_\nu L_\xi + Q_{\alpha\beta\nu\xi}^{LM} L_\nu M_\xi + Q_{\alpha\beta\nu\xi}^{MM} M_\nu M_\xi. \end{aligned}$$

Here ε^a and ε^s are the symmetric and antisymmetric parts of the dielectric tensor, the antiferromagnetic vector $\mathbf{L}$ is the difference of magnetizations of the two sublattices, $\mathbf{M}_1$ and $\mathbf{M}_2$, and $\mathbf{M}$ is the magnetic polarization $\mathbf{M}_1 + \mathbf{M}_2$ induced by the external magnetic field.

Electro-optics includes the Pockels and the Kerr effects which are, respectively, a linear and quadratic change in the refractive index of a material in response to an applied electric field. The former is allowed in crystals of the piezoelectric symmetry class only. In particular, for the electric field $\mathbf{E}^{(0)}$ applied along the $[001]$ axis of a zinc-blende-structure crystal and the light propagating along this axis, the Pockels effect induces a difference between the refractive indices of rays polarized along the $[110]$ and $[\bar{1}\bar{1}0]$ directions. The Pockels effect is the basis of the operation of Pockels cells.

Piezospectroscopy

The piezo-optical birefringence is described by the phenomenological equation

$$\delta\chi_{\alpha\beta} = P_{\alpha\beta ij} u_{ij}$$

relating a susceptibility change and the strain tensor u_{ij} . The components $P_{\alpha\beta ij} = \partial\chi_{\alpha\beta}/\partial u_{ij}$ are called the elasto-optical coefficients.

The elasto-optical tensor also describes the light scattering by acoustic phonons. In this case the components u_{ij} are considered as time-dependent strain fluctuations produced by lattice vibrations and causing fluctuations of the susceptibility. As a result, the lattice vibrations produce in the medium a transient optical superlattice which causes the Brillouin scattering of light. In a piezoelectric, $\delta\chi_{\alpha\beta}$ includes, in addition to the deformation contribution, also an electro-optical term $P_{\alpha\beta ij}^E \mathcal{E}_k$, where $P_{\alpha\beta k}^E = (\partial\chi_{\alpha\beta}/\partial \mathcal{E}_k)_{u_{ij}=0}$ is the electro-optical tensor and $\mathcal{E}$ is the electric field induced by acoustic vibrations.

Natural optical activity

If the spatial dispersion is weak, the tensor $\varepsilon_{\alpha\beta}$ may be expanded in powers of the wave vector $\mathbf{q}$. Retaining the zeroth- and first-order terms we have

$$\varepsilon_{\alpha\beta}(\omega, \mathbf{q}) = \varepsilon_{\alpha\beta}(\omega) + \gamma_{\alpha\beta\eta}(\omega) q_\eta. \quad (15)$$

In the coordinate representation the connection between $\mathbf{D}$ and $\mathbf{E}$ converts to

$$D_\alpha = \varepsilon_0 \left[\varepsilon_{\alpha\beta}(\omega) E_\beta + \gamma_{\alpha\beta\eta}(\omega) \frac{\partial E_\beta}{\partial x_\eta} \right].$$

Applying the Onsager relation we get the antisymmetric condition

$$\gamma_{\alpha\beta\eta}(\omega) = -\gamma_{\beta\alpha\eta}(\omega).$$

In the absence of dissipation, there is an additional restriction $\gamma^*_{\alpha\beta\eta}(\omega) = -\gamma_{\beta\alpha\eta}(\omega)$ and the third-rank tensor γ becomes real. Media allowing nonzero components of the tensor $\gamma_{\alpha\beta\eta}$ are said to have natural optical activity or natural gyrotropy, in contrast to the artificially induced gyrotropy in the Faraday effect.

The well-known naturally gyrotropic materials are crystal quartz and tellurium. Their point-group symmetry is D_3 , the nonzero γ tensor components are $\gamma_{xyz} = -\gamma_{yxz}$ and $\gamma_{xzy} = -\gamma_{zyx} = \gamma_{zyx} = -\gamma_{yzx}$. Similarly to the Faraday effect, a linearly polarized light propagating along the trigonal axis $C_3 \parallel z$ exhibits a rotation of the linear polarization governed by the real part of the component γ_{xyz} and ellipticity due to the imaginary part of this component. Both quartz and tellurium have enantiomorphic pairs of space groups D_3^4 and D_3^6 . The two modifications differ in sign of the tensor $\gamma_{\alpha\beta\eta}$ and, therefore, in the direction of polarization rotation.

Linear- q terms in the expansion (15) can appear due to the external influence of the static electric field (electro-gyration), strain (piezo-gyration) and magnetic field (magneto-spatial dispersion, or birefringence due to magnetic-field induced spatial dispersion).

It is important to stress the difference between the natural gyration and the Faraday gyration. In the former case the rotation angle of the light wave reflected from the bottom interface and propagating backwards decreases. In contrast, in the latter case, for the same beam of light reflected back and forth through the medium, its rotation increases each time.

Metamaterials

Electromagnetic metamaterials may be defined as a class of artificial media where the unit cell or elementary building block is small as compared to the light wavelength. More generally, a metamaterial is any material engineered to have a property that is not found in nature. We consider here negative-index metamaterials whose refractive index for an electromagnetic wave has a negative value over a certain frequency range. For this purpose it is more convenient to use the description of Maxwell's equations with two material equations. The medium is assumed to be isotropic and characterized by the relations

$$\mathbf{D} = \varepsilon_0 \varepsilon_p \mathbf{E}, \quad \mathbf{B} = \mu_0 \mu_p \mathbf{H}. \quad (16)$$

Here ε_p and μ_p are the relative electric permittivity and magnetic permeability taken to be real and frequency independent. In the description with $\mathbf{B} = \mu_0 \mathbf{H}$ instead of the second Eq. (16) they are interconnected with the relative dielectric constant by $\varepsilon = \varepsilon_p \mu_p$. The waves are propagating for a positive pair of ε_p and μ_p as well if they are both negative.

By the definition, the phase velocity $\mathbf{v}_{ph}$ of the electromagnetic wave is directed along the wave vector $\mathbf{q}$, while its group velocity $\mathbf{v}_{gr}$ complies with the direction of the Poynting vector $\mathbf{S}$. The latter is expressed by the fields $\mathbf{E}$ and $\mathbf{H}$ as follows

$$\mathbf{S} = \mathbf{E} \times \mathbf{H} = \frac{\mathbf{E} \times \mathbf{B}}{\mu_0 \mu_p}. \quad (17)$$

For a plane wave one has

$$\mathbf{S} = \frac{2\mathbf{q}}{\omega \mu_0 \mu_p} |E(\omega, \mathbf{q})|^2. \quad (18)$$

We see that, for positive values of ε_p , μ_p , the directions of $\mathbf{v}_{ph}$ and $\mathbf{v}_{gr}$ coincide. For negative ε_p and μ_p , the two velocities are antiparallel. This means, for example, that if the energy flux of an electromagnetic wave is directed along the z axis, the wave vector of this wave equals $q = n\omega/c$ with the negative refractive index $n = -\sqrt{\varepsilon}$. Media with negative permittivity and permeability form one class of metamaterials.

Another class of negatively refracting materials are resonant chiral structures, e.g., gyrotropic (chiral) media filled with resonant electric dipoles. Negative refraction has also been demonstrated in hyperbolic metamaterials which are uniaxial solids with either $\varepsilon_{\parallel} < 0$ and $\varepsilon_{\perp} > 0$ or $\varepsilon_{\parallel} > 0$ and $\varepsilon_{\perp} < 0$.

Coulomb interaction effects

In Section "Intraband absorption" we followed the single-particle Bloch scheme describing the independent motion of charge-carrying electrons and holes. The allowance for the electron-hole Coulomb interaction substantially modifies the near-band-edge absorption.

Similarly to a hydrogen atom, an electron and a hole in semiconductors form bound states, the Wannier-Mott excitons, with the excitation energy below the band gap, and the interband light absorption spectrum consists of a series of discrete levels of bound exciton states below the band gap E_g and a continuum due to unbound but correlated electron-hole pairs above the band edge. As a result the absorption edge becomes red-shifted by the ground-state exciton binding energy.

The wave function of the Wannier-Mott exciton can be decomposed into the states of noninteracting electron-hole pairs as follows

$$\Psi^{exc} = \sum_{s\mathbf{k}_e, m\mathbf{k}_h} C_{s\mathbf{k}_e, m\mathbf{k}_h} |s\mathbf{k}_e, m\mathbf{k}_h\rangle. \quad (19)$$

Here s, m are the indices identifying the conduction- and valence-band spin branches, $\mathbf{k}_{e,h}$ is the electron or hole wave vector, $|\mathbf{s}\mathbf{k}_e, \mathbf{m}\mathbf{k}_h\rangle$ is the excited state of the crystal in which only one conduction-band state $|\mathbf{s}\mathbf{k}_e\rangle$ is occupied and only one valence state $\hat{K}|\mathbf{m}\mathbf{k}_h\rangle$ is empty. Here $\hat{K}$ is the time inversion operator $-\mathrm{i}\sigma_y\mathcal{K}_0$, σ_y the second spin Pauli matrix and $\mathcal{K}_0$ the complex conjugation operation. By the envelope wave function of the exciton in the real-space representation, or the $\mathbf{r}$ -representation, one understands the function obtained by inverse Fourier transform

$$\varphi_{sm}^{\text{exc}}(\mathbf{r}_e, \mathbf{r}_h) = \sum_{\mathbf{k}_e, \mathbf{k}_h} e^{\mathrm{i}(\mathbf{k}_e \cdot \mathbf{r}_e + \mathbf{k}_h \cdot \mathbf{r}_h)} C_{\mathbf{s}\mathbf{k}_e, \mathbf{m}\mathbf{k}_h}. \quad (20)$$

For the simple (parabolic and isotropic) conduction and valence bands, the envelope functions are hydrogen-like. For example, the ground-state exciton, or 1 s -exciton, is described by the envelope

$$\varphi_{1s}^{\text{exc}}(\mathbf{r}_e, \mathbf{r}_h) = \frac{e^{\mathrm{i}\mathbf{K} \cdot \mathbf{R}}}{\sqrt{V}} \varphi_{1s}(\mathbf{r}), \quad \varphi_{1s}(\mathbf{r}) = \frac{e^{-r/a_B}}{\sqrt{\pi a_B^3}}. \quad (21)$$

Here we use the notation V for the crystal volume, $\mathbf{R}$ for the exciton center of mass $(m_e \mathbf{r}_e + m_h \mathbf{r}_h)/(m_e + m_h)$, $m_{e,h}$ for the electron or hole effective masses, $\mathbf{K}$ for the exciton translational wave vector, r for $|\mathbf{r}_e - \mathbf{r}_h|$, and a_B for the exciton Bohr radius $\varepsilon \hbar^2/(\mu_{cv} e^2)$.

The excitation energy of exciton state with the principal quantum number $n = 1, 2, \dots$ is $E = E_g - R_{\text{exc}}/n^2 + \hbar^2 K^2/2M$, where M is the exciton translational mass $m_e + m_h$, and R_{exc} is ground-state 1 s -exciton binding energy, or exciton Rydberg, given by $(\mu_{cv}/m_0) \varepsilon^{-2} R_\infty$, $R_\infty = 13.6$ eV is the Rydberg energy constant, ε is the dielectric function at the frequency $\Omega \sim R_{\text{exc}}/\hbar \ll E_g/\hbar$.

For the above-gap electron-hole excitations, a residual effect of the Coulomb mutual attraction of an electron and a hole gives rise to a correlation of their positions in space and an enhanced wave function overlap. This enhances the optical transition matrix elements compared to the negligible electron-hole interaction and affects the spectral shape of the continuum absorption spectrum at $\hbar\omega > E_g$. The ratio of the absorption coefficients above the band edge with and without the Coulomb interaction is called the Sommerfeld factor or the Coulomb enhancement factor. In a three-dimensional (3D) semiconductor, due to this factor the absorption coefficient changes the square-root dependence (11) to a constant absorption closely above the bandgap. In a two-dimensional (2D) system, the bare band-to-band step absorption spectrum is multiplied by the 2D Sommerfeld factor which equals 2 at the gap edge and unity far above the gap. In both 3D crystals and 2D semiconductors, III-V and II-VI based quantum wells, the changes in the absorption spectrum are seen in the range of a few exciton Rydberg energies.

In dielectrics, e.g. ionic and molecular crystals, the photoexcited electron and hole are tightly bound to each other within the same unit cell or nearest-neighbor unit cells and form the Frenkel excitons. Due to the dipole-dipole interaction, intra-cell excitation is transferred to other cells and propagates in the crystal. The optical spectra of Frenkel excitons in molecular crystals with more than one equivalent molecular entity in the unit cell reveal the so-called Davydov splitting. A notable example of excitons of the intermediate type are charge-transfer excitons. All types of excitons possess a common property: the free exciton is an electron excitation which involves correlated motion of electrons and holes, does not carry current, but does carry energy.

Fine structure of exciton levels

If allowance is made for free-carrier spin, then the ground state $n = 1$ of an exciton is degenerate, even in the case of simple bands. For direct-gap Γ -point excitons, the ground-state degeneracy is equal to the product of the conduction- and valence-band degeneracies at $\mathbf{k} = 0$. The wave functions of the ground state transform according to the representation $D_{\text{exc}} = \Gamma_e \times \Gamma_h$, where the representations Γ_e and Γ_h characterize the symmetry of electron and hole states at the extremum point. The representation D_{exc} is reducible and may be decomposed into irreducible representations of the point group of the bulk or nanostructure material. The electron-hole exchange interaction partially removes the degeneracy and splits the 1 s -exciton level into states transforming according to the irreducible representations.

For illustration, let us consider a pair of the conduction band Γ_6 and the heavy-hole valence band Γ_6 in a zinc-blende-based quantum well structure of the D_{2d} symmetry. In accordance with the multiplication law $\Gamma_6 \times \Gamma_6 = \Gamma_1 + \Gamma_2 + \Gamma_5$ we obtain that the heavy-hole exciton level 1 s is split into a doubly degenerate state Γ_5 active in the polarization perpendicular to the C_2 axis and two dipole-forbidden singlet levels Γ_1 and Γ_2 .

Optical properties of two-dimensional systems

The Bouguer law is unadapted to two-dimensional structures. In this case the absorption property is conveniently described by the absorptance A defined as a ratio of the absorbed radiant flux to the incident flux. For a 2D graphene flake lying on the substrate with the refractive index n the absorptance takes the form

$$A = f \frac{\pi e^2}{\hbar c},$$

where $f = 4/(n+1)^2$. For a free-standing flake where $f = 1$ the absorptance has a universal value of the fine structure constant $e_2/(\hbar c)$ times π . The calculation shows that, with allowance for the electron-electron Coulomb interaction, the coefficient A is renormalized

by a factor $1 + \mathcal{D}g$, where the interaction strength parameter $g = e^2/(n^2/\hbar v_0)$, v_0 is the so-called Fermi velocity, and $\mathcal{D} = (19 - 6\pi)/12 \approx 0.0125$. Thus, in graphene the Coulomb renormalization is negligible.

In bulk semiconductors an exciton polariton is formed by a 3D exciton and a 3D photon, see the next section. Nanostructures of different dimensionalities allow one to study coupling between 3D photons and 2D, 1D or 0D excitons. The coupling between a 3D photon and a 2D exciton is realized in a quantum well (QW) structure. The coefficient of amplitude reflection and transmission of light from a single QW is given by

$$r_{QW} = \frac{i\Gamma_0}{\omega_0 - \omega - i(\Gamma_0 + \Gamma)}, \quad (22)$$

where ω_0 , Γ_0 and Γ are the exciton resonance frequency, radiative and nonradiative decay rates. The meaning of these parameters can be conveniently interpreted in terms of the time-resolved experiment: after a short-pulse photoexcitation of the exciton the time variation of its wave function is described by the factor $\exp[-(i\omega_0 + \Gamma + \Gamma_0)t]$. The parameter Γ_0 enters both the numerator and denominator and can be thought of as the exciton oscillator strength. The amplitude transmission coefficient is related to the reflection coefficient by $t_{QW} = 1 + r_{QW}$ which leads to the QW absorptance

$$A = 1 - |r_{QW}|^2 - |t_{QW}|^2 = \frac{2\Gamma_0\Gamma}{(\omega_0 - \omega)^2 + (\Gamma_0 + \Gamma)^2}.$$

The reduced dimensionality of nanostructures gives rise to an increased charge carrier interaction leading to high exciton binding energies. The quantum confinement of electron and hole wave functions enhances the exciton oscillator strength and supports the existence of exciton complexes such as biexcitons and trions. Biexciton is a positronium-molecule-like four-body system of two electrons and two holes. There are both the negatively and positively charged trions, X^- and X^+ , composed of two electrons and one hole or two holes and one electron, respectively. The complexes, called originally "excitonic molecule" and "excitonic ion," are analogous, respectively, to a hydrogen molecule H_2 and to an ion H^- or ionized molecule H_2^+ .

The trions can be optically excited in the systems containing resident charge carriers. In the reflection spectra they are observed as an additional resonant contour below the exciton resonance. In such two-pole reflection spectrum, the amplitude reflection coefficient near the trion resonance is also described by Eq. (22) where ω_0 and Γ_0 are replaced by the trion resonance frequency ω^t_0 and the radiative damping rate Γ^t_0 , the latter being proportional to the density of resident carriers. With the increasing density, the enhancement in the trion oscillator strength Γ^t_0 is accompanied by a decrease in the exciton oscillator strength Γ_0 .

The biexciton binding energy ε_{bi} is defined as the difference between the biexciton excitation energy $\hbar\omega^{bi}_0$ and two ground-state exciton energies $2\hbar\omega_0$. Biexciton forms mainly through the following three mechanisms: (i) two-photon absorption, (ii) - exciton-exciton binding in condensed exciton environment, and (iii) resonant excitation from a single exciton.

Polaritons

The optical properties of bulk solids are strongly modified in the vicinity of the resonance frequency of the quasi-particle excitation such as optical phonon or exciton. A photon and a quasi-particle mix in the dispersion-crossover region, losing their identity in a combined quasi-particle called the polariton, phonon polariton or exciton polariton, satisfying the dispersion Eq. (7).

Phonon polaritons

We start from the optical spectroscopy of optical phonon polaritons and consider a crystal lattice of cubic symmetry with two distinct atoms per unit cell. In such a material the optical phonons are infrared-active and the dielectric function has the Lorentz type of dispersion

$$\varepsilon(\omega) = \varepsilon^\infty + \frac{(\varepsilon^0 - \varepsilon^\infty)\omega_T^2}{\omega_T^2 - \omega^2 - i\omega\Gamma}, \quad (23)$$

where ε^0 and ε^∞ are static and high frequency dielectric constants, ω_T is the resonant frequency of the transverse optical phonon, or the TO phonon, and Γ is the phonon decay rate. Note that the existence of a bandgap in an insulator is confirmed by the optical transparency below this bandgap, except in the lower energy region where the absorption is due to lattice vibrations because in realistic materials $\Gamma \neq 0$ and the imaginary part of the dielectric function is nonzero.

Neglecting the decay, we can rewrite Eq. (23) as

$$\varepsilon(\omega) = \varepsilon^\infty \frac{\omega_L^2 - \omega^2}{\omega_T^2 - \omega^2}, \quad (24)$$

where the longitudinal phonon frequency ω_L is given by Lyddane-Sachs-Teller relation

$$\frac{\omega_L^2}{\omega_T^2} = \frac{\varepsilon^0}{\varepsilon^\infty}.$$

Physically, polaritons can be conveniently considered in terms of an effective two-oscillator model. Particularly, in a phonon polariton, the uncoupled photonic and phononic oscillators are characterized by the same wave vector $\mathbf{q}$ and the bare-particle eigen

Fig. 2 Optical properties of a GaP crystal in the infrared region. (A) Normal-incidence reflectivity calculated for the following set of parameters: $\varepsilon^\infty = 9.08$, $\omega_T = 364.81 \text{ cm}^{-1}$, $\omega_L = 402.33 \text{ cm}^{-1}$, $\Gamma = 1.61 \text{ cm}^{-1}$. (B) Ellipsometric phase shift Δ at 70° angle of incidence versus photon energy. The parameters are taken from Samarasingha and Zollner, 2021.

frequencies ω_T and $\omega_{\text{phot}} = cq/\sqrt{\varepsilon^\infty}$. The coupling is governed by the value of the phonon longitudinal-transverse splitting, $\omega_{LT} = \omega_L - \omega_T$. The two-oscillatory analogy is clearly seen in a rewritten version of Eqs. (7) and (24)

$$(\omega^2 - \omega_{\text{phot}}^2)(\omega^2 - \omega_T^2) = \omega^2(\omega_L^2 - \omega_T^2).$$

In the general consideration, the numerator and denominator in Eq. (24) contain the terms $-i\omega\Gamma_L$ and $-i\omega\Gamma_T$ with different decay rates Γ_T and Γ_L .

Fig. 2 shows the infrared reflection spectrum of a GaP bulk crystal under normal incidence and the phase shift Δ as a function of photon energy calculated at the incidence angle 70° .

Since in the interval $\omega_T < \omega < \omega_L$ (the so-called Reststrahlen region) the dielectric function (24) is negative and, therefore, the refractive index $\bar{n}$ is imaginary, the reflectance $R = 1$. Moreover, at the frequency $\omega = \sqrt{(\varepsilon^\infty - 1)/(\varepsilon^0 - 1)}\omega_T < \omega_T$ the refractive index $\bar{n}$ equals to unity and the reflection vanishes, $R = 0$. With increasing frequency above ω_L , the reflectivity saturates and is determined by the high-frequency refractive index $n = \sqrt{\varepsilon^\infty}$. Evidently, with allowance for the phonon decay rate Γ the reflection spectra are smoothed.

Exciton polaritons

For excitons, the longitudinal-transverse splitting ω_{LT} is small as compared with the resonance frequency ω_0 and the dielectric function in the vicinity of ω_0 can be reduced to

$$\varepsilon(\omega, \mathbf{q}) = \varepsilon_b \left(1 + \frac{\omega_{LT}}{\omega_0(\mathbf{q}) - \omega - i\Gamma} \right).$$

Here ε_b is the background dielectric constant, and as compared with Eq. (23) we take into account the spatial dispersion, namely, the dependence of the exciton resonance frequency on the wave vector: $\omega_0(\mathbf{q}) = \omega_0 + (\hbar q^2/2M)$. The consequence is that the dispersion Eq. (7) becomes a second-order algebraic equation for q^2 with two solutions, photon-like and exciton-like polaritons. For the calculation of the reflectivity, the Maxwell boundary conditions must be supplemented with an additional boundary condition. The theory of exciton polaritons is applicable to both the Wannier–Mott and Frenkel excitons. However, the exciton wave function and fine structure of excitonic levels are certainly treated quite differently in these two models.

For the Wannier–Mott exciton wave function (21), the longitudinal-transverse splitting is given by

$$\omega_{LT} = \frac{4\pi}{\hbar\varepsilon_b} \left(\frac{ep_{cv}}{\omega_0 m_0} \right)^2 \varphi_{1s}^2(0). \quad (25)$$

where $\varphi_{1s}(0) = (\pi a_B^3)^{-1/2}$ is the probability amplitude that the electron and the hole are found on the same site which is nonvanishing only for the s -like states. This equation is true if the interband matrix element of the momentum operator p_{cv} taken between the conduction and valence bands at the extremum point is nonzero. By contrast, in Cu_2O crystals the interband matrix elements vanish at the extremum point and depend linearly on the electron wave vector $\mathbf{k}$. In this case the exciton oscillator strength of the s -excitons vanishes and optically active are the p -excitons. This explains why, in Cu_2O , the exciton absorption peaks start from the principal number $n = 2$. In the same way, the two-photon optical transitions are forbidden for the s -excitons and allowed for p -shell excitons if the matrix element p_{cv} is nonzero at the extremum point and the s -excitons are optically active in one-photon absorption. Fig. 3 shows the one-photon absorption spectrum of the p -excitons obtained from the transmission experiments, revealing a large number of lines (Kazimierzuk et al., 2014). To take a closer look at the high-energy part, the spectrum is zoomed with increasing resolution.

Reproduced by permission Kazimierz T, Fröhlich D, Scheel S et al. (2014) Giant Rydberg excitons in the copper oxide Cu_2O . *Nature* 514: 343–347, doi: 10.1038/nature13832.

Polaritons in quantum microcavities

The modern technology allows one to reduce the dimensionality of photonic quantum states. Particularly, a 2D photon is realized in a planar optical microcavity which is a multilayer heterostructure consisting of an active layer sandwiched between left-hand and right-hand distributed Bragg reflectors. If one or few QWs are embedded inside the active layer, the structure is called the quantum microcavity. The cavity exciton-polariton is a generalization of the concept of exciton polariton in a bulk material and can be also modeled by a pair of two coupled classical oscillators, one representing a 2D photon mode and another representing a 2D exciton in the QW. In the simplest case of a single QW placed inside the active layer, the eigen-frequencies $\omega_{\pm}$ of two 2D exciton-polariton modes are two solutions of the equation

$$\left[\omega - \bar{\omega}(q_{\parallel}) + i\bar{\gamma} \right] (\omega - \omega_0 + i\Gamma) = V^2. \quad (26)$$

Here $q_{\parallel}$ is the in-plane wave vector, ω_0 and Γ are the exciton resonance frequency and nonradiative damping rate, $\bar{\omega}(q_{\parallel}) = \sqrt{\tilde{\omega}^2 + (cq_{\parallel}/n_b)^2}$, $\bar{\omega}$ and $\bar{\gamma}$ are the resonance frequency and damping rate of the photon mode, $n_b^2 = \epsilon_b$ is the dielectric constant of the active layer, the coupling parameter V determines the so-called Rabi splitting $2V$. In the strong-coupling regime, $(\Gamma - \bar{\gamma})^2 < (2V)^2$, the two eigen-frequencies of Eq. (26) reveal themselves as two dips in the reflection spectra and peaks in the transmission or absorption spectra.

Resonant photonic crystals

Photonic crystals are media with the dielectric constant periodically varying in space with a period allowing for the Bragg diffraction of light in the visible or infrared range. In this context, a simplest example of a photonic (one-, two-, or three-dimensional) crystal is a periodic structure consisting of two materials with different refractive indices, like a distributed Bragg reflector. Natural opal gemstones and artificial opals represent 3D photonic crystals. Similarly to X-ray diffraction in conventional crystals, the photonic crystals allow for diffraction for optical wavelengths.

Of particular interest are periodic structures, in which the dielectric response of one of the structural blocks as a function of frequency has a pole at a certain resonance frequency ω_0 . They form a special class of resonant photonic crystals. In these systems, normal light waves are polaritons. The resonant Bragg structure is a special kind of multiple QWs with the period d satisfying the condition

$$q(\omega_0) = \frac{\pi}{d} \quad \text{or} \quad d = \frac{\lambda(\omega_0)}{2},$$

where $q(\omega) = \omega n_b/c$ and $\lambda(\omega_0) = 2\pi c/\omega_0 n_b$ are the light wavevector and wavelength at the exciton resonant frequency, $n_b = \sqrt{\epsilon_b}$. Evolution of the reflection spectrum of the resonant Bragg structure with the QW number N demonstrates a transition from the superradiative regime, $N \ll \sqrt{\omega_0/\Gamma_0}$, to the photonic-crystal regime, $\sqrt{\omega_0/\Gamma_0} \ll N$. In the former regime, the reflectance is given by Eq. (26) where Γ_0 is simply replaced by $N\Gamma_0$. In the latter regime, the structure shows itself as a true photonic crystal with a stop-band of the width $2\sqrt{2\Gamma_0\omega_0/\pi}$.

Photoluminescence

Photoluminescence is the emission of radiation induced by the optical excitation of a sample by using an external source of light. The conventional photoluminescence spectroscopy is based on measurements of secondary-emission spectrum at fixed parameters of the primary radiation. In this set-up the measured spectrum is mainly determined by the oscillator strength and occupancy of the radiative states. In its turn, the occupancy is controlled by the lifetime and energy relaxation processes of charge carriers and excitons. In another technique, known as photoluminescence excitation spectroscopy, the spectrometer is set to detect emission of a fixed photon energy from the sample. The intensity of this emission is recorded as a function of the excitation photon energy. Photoluminescence excitation spectra give information about the absorption spectrum above the fundamental edge, rather than about the lifetimes of excited states.

In particular cases of resonant optical excitation a secondary-emission process can be considered both as the photoluminescence and light scattering. On the other hand, as in light scattering the spectrum of the secondary radiation is tied to the initial light frequency and shifts with shifting this frequency. On the other hand, the same process has features of the photoluminescence because it can be described in terms of a two-step process with a real intermediate state. On this basis, sometimes the general term “resonant secondary emission” is used. In most cases, however, the difference between the two phenomena can be justified. Indeed, in light scattering defined in the traditional way the excited states of a system are virtual, whereas in conventional photoluminescence the emission of the secondary photon is usually preceded by multiple transitions of the system between different real excited states.

Color centers

Insulating crystals with point defects of a lattice (impurity atoms or ions, vacancies etc.) represent a special class of optical materials. The defects introduce additional energy levels lying between the conduction-band bottom and valence-band top, so that lower-energy photons are allowed to participate in absorption processes. Crystal defects can form color centers and allow for both the spontaneous and stimulated emission of light at new wavelengths. In alkali halides, a color center formed by an electron trapped in an anion vacancy is called the F center. Alternatively, completely transparent crystals and glasses exhibit pronounced colors by doping with ions often called activators.

The photoluminescence (or fluorescence) of defects in an insulating solid, e.g. F center in an alkali halide, is characterized by the Stokes shift which means that the fluorescence emission occurs at a longer wavelength than the incident light. The explanation is given in the configuration coordinate model. Once excited, the electron trapped by the vacancy causes significant displacements of nearby atoms to their new equilibrium positions (lattice relaxation). From this “relaxed excited state,” the electron returns to the ground state emitting a photon. The peak of the emission band is displaced from that of the absorption band by the Stokes shift, both bands being described by Gaussian-like shape. In the model both the optical excitation and radiative recombination follow the Franck–Condon principle which, classically, states that an electronic transition is most likely to occur without changes in the positions of nuclei in the surrounding environment.

The ruby laser was the first with which laser radiation was generated at a wavelength of 694.3 nm. It uses a solid medium of crystalline aluminum oxide Al_2O_3 containing chromium ions which replace Al atoms. When light is incident on the Cr^{3+} ion, an electron is raised from its ground state 4A_2 to its excited states 4T_2 and 4T_1 lying roughly at 2.2 eV and 3.0 eV above the ground state, respectively. These states decay non-radiatively by phonon emission until the electron reaches its lowest excited metastable state 2E which on a transition to 4A_2 ground state emits the laser radiation. Historically, the second laser material was uranium-doped calcium fluoride $\text{U}^{3+}:\text{CaF}_2$, and then the neodymium-doped calcium-tungstate (CaWO_4) laser was made emitting on the now-standard 1.06 - μm transition.

Point defects in glasses are atomic size deviations of the short range order (intrinsic defects) and the isolated impurity atoms or ions in the glass network (impurity defects). In an ideal structure of glass, the lattice is defined as solid network, in which each atom has the same short range order. For example, in the fused silica glass network (SiO_2) each silicon atom is tetrahedrally surrounded by four oxygen atoms and each oxygen atom is surrounded by two silicon atoms. In this optical glass, the broad transparent transmission range covers the complete visible spectrum and extends far into the infrared and ultraviolet regions where electronic and vibronic absorption takes place. The existence of point defects usually manifests as changes of spectroscopic properties in the transparency region. Mainly all glass-based lasers act on electronic transitions between impurity defect (activator) levels.

Optical orientation of electron spins

Since the pioneer work by Lampel (1968) the optical orientation of free-carrier spins in semiconductors has become an effective method, contactless and nondestructive, for investigations of semiconductor band structure and kinetic parameters. The essence of the method is to analyze the photoluminescence polarization as a function of the polarization of the initial light. We first formulate the basics of optical orientation of free-carrier spins. For simplicity we assume that the light propagates along the normal z to the sample surface and the luminescence is registered in the backscattering geometry. We use also the following notations: P_c^0 for the degree of circular polarization of the initial light, $n_{\pm}$ for the densities of electrons with the spin up and down with respect to the z direction, n for the total electron density $n_+ + n_-$, $g_{\pm}$ for the partial photogeneration rates, g for the total electron generation rate $g_+ + g_-$, S_z for the total electron spin polarization $(n_+ - n_-)/2$, and p for the degree of the spin polarization $(n_+ - n_-)/(n_+ + n_-)$.

Spin photoexcitation

Under optical interband excitation by circularly polarized light, the angular momentum component of σ_+ (or σ_-) photons is transferred to the spin of free carriers. The spin polarization of the photogenerated electrons depends on the selection rules for the interband transitions. The initial degree of spin polarization, $p_0 = (g_+ - g_-)/(g_+ + g_-)$, is proportional to the degree of circular polarization of the initial light: $p_0 = \kappa P_c^0$. The coefficient κ depends on the selection rules: for the interband transitions $\Gamma_8 \rightarrow \Gamma_6$ in the bulk GaAs-type semiconductors $\kappa = -1/2$, while for the optical transitions from the heavy-hole valence subband in a GaAs-based quantum well structure $\kappa = -1$.

Electron spin kinetics

The rate equations for the densities n_+ and n_- have the form

$$\begin{aligned} \frac{dn_+}{dt} + \frac{n_+}{\tau_0} + \frac{1}{2\tau_s}(n_+ - n_-) &= g_+, \\ \frac{dn_-}{dt} + \frac{n_-}{\tau_0} + \frac{1}{2\tau_s}(n_- - n_+) &= g_-. \end{aligned} \quad (27)$$

Here τ_0 is the lifetime of photoelectrons in the conduction band and τ_s is the spin relaxation time. Under steady-state excitation, the solution of the above rate equations reads $n = g\tau_0$ and $p = (T/\tau_0)p_0$, where T is the lifetime of optically oriented spins defined by $T^{-1} = \tau_0^{-1} + \tau_s^{-1}$. If the photoelectron lifetime τ_0 is not too long as compared to the spin relaxation time τ_s , then the photoelectrons retain spin polarization (at least partially).

Photoluminescence polarized by the optical orientation

Due to the same selection rules for interband optical transitions, the radiative recombination of spin-polarized photocarriers gives rise to a (partial) circular polarization of the photoluminescence $P_c = \kappa p$. This equation is valid for recombination with unpolarized holes which takes place in bulk GaAs, where the hole spin relaxation is very fast. In quantum well structures, the holes also can retain their spin polarization. If the both electron and hole degrees of spin polarization, p_e and p_h , are nonzero, the circular polarization (in a GaAs quantum well) is given by a more complicated equation

$$P_c = \frac{p_h - p_e}{1 - p_e p_h}.$$

Magnetic field influence

The transverse magnetic field, $\mathbf{B}^{(0)} \perp z$, leads to depolarization of the photoluminescence. The rate equation for the spin polarization S in the transverse magnetic field can be written down in the form

$$\frac{S}{T} + S \times \Omega_L = G_s, \quad (28)$$

where $\Omega_L = g_e \mu_B \mathbf{B}^{(0)}/\hbar$ is the Larmor frequency, g_e is the electron's effective g factor, and G_s is the spin generation rate.

Let $\mathbf{B}^{(0)} \parallel x$, then under the normal incidence, $G_s \parallel z$, one has

$$S_z(B^{(0)}) = \frac{S_z(0)}{1 + (\Omega_L T)^2}, \quad S_y(B^{(0)}) = -\frac{\Omega_L T}{1 + (\Omega_L T)^2} S_z(0), \quad S_x = 0,$$

where $S_z(0)$ is the spin polarization at zero magnetic field. One can see that in the transverse magnetic field the average electron spin is rotated around $\mathbf{B}^{(0)}$ and depolarized. This is the so-called Hanle effect. By measuring the photoluminescence intensity and analyzing its circular polarization in the transverse magnetic field, one can extract the characteristic time parameters τ_0 and τ_s .

Similarly to free carriers, exciton spins (or angular momenta) can be optically oriented as well by circularly polarized light. The circular polarization of the exciton photoluminescence is governed by the exciton lifetime and spin relaxation time.

Spin and valley optical orientation in transition metal dichalcogenides

In a monolayer of transition metal dichalcogenides, e.g. MoS₂, the spin orientation is accompanied by the valley polarization which is an inherent property of their band structure. In these atomically thin direct-gap materials, the conduction- and valence-band extrema are located not at the center of the two-dimensional hexagonal Brillouin zone, but rather at its vertices K_+ and K_- . Due to the spin-orbit interaction, the spin sublevels in the conduction and valence bands are remarkably split even at the extremum points with the opposite signs of the splitting in the $K_{\pm}$ valleys. As a result, under optical excitation by circularly polarized light near the band edge E_g the spin-polarized photocarriers and excitons are generated either in the K_+ valley or in the K_- valley depending on the sign of circular polarization, σ_+ or σ_- .

Magnetic circular polarization of exciton photoluminescence

The exchange interaction leading to the splitting of excitonic levels leaves some sublevels degenerate. In an external magnetic field, an additional modification of the exciton spectrum occurs, in particular, the remaining degeneracy of the exciton states is removed (Zeeman effect). Each of the split, optically active states emits circularly or elliptically polarized light in the direction of the magnetic field. In majority of situations, the exciton luminescence bandwidth exceeds the exchange and Zeeman splitting of exciton levels, due to the inhomogeneous broadening of the exciton's resonance frequency. This situation takes place when excitons are localized on deep levels in bulk crystals, composition fluctuations in solid solutions, fluctuations of the width of quantum wells, interfaces of a type II superlattice, and also in the case of size quantum effects for excitons in quantum dots or colloid nanocrystals allowing for the dispersion of their size and shape within the illuminated spot. This spectrally hidden fine structure manifests itself in the magnetic circular polarization of luminescence and in the dependence of the luminescence intensity on the magnetic field. The polarization appears due to a thermal selective population of split exciton spin levels. The optical spin orientation discussed in the previous section is most clearly observed under conditions, where the spin relaxation time τ_s is longer than the lifetime τ_0 . In contrast to the optical orientation, the magnetic circular polarization of luminescence is high in the opposite case, $\tau_s < \tau_0$, when the populations of the Zeeman sublevels are quasi-equilibrium.

Purcell effect

The Purcell effect in the broad sense is the enhancement of a quantum system's spontaneous emission rate by its environment. For a point light source inserted into a photon resonant cavity, the effect is described by the Purcell factor f defined as the ratio between lifetimes of spontaneous emission in the infinite homogeneous medium filled with the cavity material and in a system with the cavity. Under the optimal conditions, where the resonance frequency of the emitter ω_0 is tuned to the cavity photon frequency ω_c and the emitter is placed in the field antinode, the Purcell factor is given by

$$f = \frac{3Q\lambda^3}{4\pi^2 V},$$

where V is the volume of the resonator, Q is the quality factor, $\lambda \equiv \lambda_0$ is the light wavelength in vacuum if the cavity is empty and $\lambda = \lambda_0/n$ if the cavity is filled with a substance with the refractive index n .

Single-photon sources

Single-photon emitters are non-classical light sources. The promising types are atom-like solid-state single-photon emitters including fluorescent atomic defects (in diamond, SiC, Nd-doped Y₃Al₅O₁₂ garnet, Y₂SiO₅, ZnO, BN), semiconductor quantum dots and nanocrystals (InAs, GaN, core/shell CdSe/ZnS), localized excitons in two-dimensional materials (WSe₂, MoSe₂ monolayers) and carbon nanotubes. If the sample contains plenty of isolated light sources, e.g., quantum dots, at low enough density they can be isolated to be used as a single-photon emitter.

One of the most important characteristics of light sources is the second order correlation function $g^{(2)}(\tau)$, which can be measured in the Hanbury-Brown-Twiss experiment. Here τ is the photon pair separation time. If a two-level quantum system emits a photon at a time t , it is impossible for it to emit another one immediately after that, because it is necessarily in the ground state. The next photon can only be emitted after a waiting time. In an ideal single-photon source, the function $g^{(2)}(\tau)$ vanishes at $\tau \rightarrow 0$ (the photon antibunching effect) and is described by $1 - \exp[-t(\Gamma + W)\tau]$, where Γ is the electron-hole recombination rate and W is the effective generation rate of the quantum system.

Two-photon entanglement

Quantum entanglement is a physical phenomenon that occurs when, in two or more particles, the quantum state of each particle cannot be described independently of the state of the others, including even when the particles are separated by a large distance. The simplest example of an entangled photon pair is the quantum-mechanical state

$$\Psi = \frac{1}{\sqrt{2}}(|\hbar\omega_1, \sigma_+\rangle|\hbar\omega_2, \sigma_-\rangle + |\hbar\omega_1, \sigma_-\rangle|\hbar\omega_2, \sigma_+\rangle), \quad (29)$$

where $|\hbar\omega_j, \sigma_\pm\rangle$ is a single photon state of the energy $\hbar\omega_j$ ($j = 1, 2$) and right- or left-hand circular polarization. Note that these photons can propagate in arbitrary relative directions.

Entangled photons on demand can be generated in the biexciton-exciton radiative cascade in a single semiconductor quantum dot. In the biexciton ground state, two electrons or two holes form spin singlet states. Starting from this ground state, one of the electrons recombines with a hole and emits a σ_+ or σ_- photon. Then the second electron of the opposite spin recombines with the second hole of the opposite spin, and, due to the selection rules, a photon of opposite polarization is emitted. Because of the interparticle interaction, the biexcitonic ground state has an energy $\hbar\omega_{bi}$ different by few meV from the doubled energy $2\hbar\omega_0$ of excitonic ground state. Therefore, the first emitted photon 1 and the second emitted photon 2 have different energies $\hbar\omega_1$ and $\hbar\omega_2$.

If instead of circular polarization the linear polarization is analyzed, the state (29) can be written down in an equivalent form as $(\hbar\omega_1, X)|\hbar\omega_2, X\rangle + |\hbar\omega_1, Y|\hbar\omega_2, Y\rangle)/\sqrt{2}$ in which case the entangled photons are collinearly polarized in the x or y directions.

Nonlinear optics

Many nonlinear effects can be phenomenologically described by expanding the electric polarization in powers of the light-wave electric field $\mathbf{P} = \mathbf{P}^{(1)} + \mathbf{P}^{(2)} + \mathbf{P}^{(3)} + \dots$. The first term describes the conventional linear response (4). The second and third terms represent the nonlinear responses of the second and third orders

$$\begin{aligned} P_\alpha^{(2)}(\mathbf{r}, t) &= \varepsilon_0 \chi_{\alpha\beta\gamma}^{(2)}(\omega_1, \omega_2) E_\beta(\omega_1, \mathbf{k}_1) E_\gamma(\omega_2, \mathbf{k}_2) \exp[i(\mathbf{k}_1 + \mathbf{k}_2) \cdot \mathbf{r} - i(\omega_1 + \omega_2)t], \\ P_\alpha^{(3)}(\mathbf{r}, t) &= \varepsilon_0 \chi_{\alpha\beta\gamma\delta}^{(3)}(\omega_1, \omega_2, \omega_3) E_\beta(\omega_1, \mathbf{k}_1) E_\gamma(\omega_2, \mathbf{k}_2) E_\delta(\omega_3, \mathbf{k}_3) \\ &\quad \times \exp[i(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \cdot \mathbf{r} - i(\omega_1 + \omega_2 + \omega_3)t]. \end{aligned} \quad (30)$$

Here ω_j is the frequency, $\mathbf{k}_j$ the wave vector, $E(\omega_j, \mathbf{k}_j)$ the amplitude of the j -th constituent of the electromagnetic field. For single crystals or short-period SLs, $\mathbf{r}$ is the 3D radius-vector while, in QW structures, $\mathbf{r}$ is a vector with the components x, y, z_l , where z_l is the position of the l -th well, for instance, the coordinate of its center (the choice of point z_l within a well is arbitrary if its width is small compared with the light wavelength). The frequencies in Eq. (30) may assume both positive and negative values, the corresponding amplitudes being related through

$$E(-\omega, -\mathbf{k}) = E^*(\omega, \mathbf{k}).$$

For the sake of simplicity, we neglect in Eq. (30) the spatial dispersion of the susceptibility, i.e., the dependence of $\chi^{(n)}$ on $\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3$.

The second-order susceptibility $\chi^{(2)}$ describes the generation of optical harmonics at the sum or difference frequency, in particular, at $\omega_1 = \omega_2$, second-harmonic generation. The dc photogalvanic current $\mathbf{j}$ is obtained from $\chi^{(2)}$ in the limit $\omega_2 \rightarrow -\omega_1$.

Fig. 4 shows the intensity of the second harmonic generation (SHG) observed in the magnetoelectric antiferromagnet CuB_2O_4 (Mund et al., 2020). The exciting laser light is polarized along the z axis, the electric field of the second harmonic $E^{2\omega} \parallel x$, the external magnetic field $\mathbf{B}^{(0)}$ is directed either along or against the x axis. The difference $|E^{2\omega}(\mathbf{B}^{(0)})|^2 - |E^{2\omega}(-\mathbf{B}^{(0)})|^2$ demonstrates the nonlinear nonreciprocity effect described by the product $B_x^{(0)} T_x |E_z^\omega|^4$, where T is the toroidal vector expressed via the antiferromagnetic vector $\mathbf{L}$ as $T = \hat{e}_x L_y - \hat{e}_y L_x$.

Fig. 4 Second harmonic generation spectra measured in CuB_2O_4 , at $T = 4$ K for opposite magnetic fields demonstrates a strong spectral nonreciprocity reaching almost 100% at some lines, e.g., at 1.4062 eV line. The right-hand part shows geometry of the experiment. Reproduced by permission Mund J, Yakovlev DR, Poddubny AN et al. (2020) Toroidal nonreciprocity of optical second harmonic generation. *Phys. Rev. B* 103: 180410.

The third-order susceptibility $\chi^{(3)}$ describes a variety of phenomena, namely, third-harmonic generation (at $\omega_1 = \omega_2 = \omega_3$), two-photon absorption of a monochromatic light wave (two of the three values of ω_j coincide, the third one differs from them in sign, e.g., $\omega_2 = \omega_3 = -\omega_1$) or two monochromatic waves (two of the three frequencies differ in sign and do not coincide with the third one, e.g., $\omega_2 = -\omega_3 \neq \pm\omega_1$), a photoinduced change in the absorption or reflection of a probe beam linear in pump-beam intensity (photoabsorption or photoreflexion), photoinduced gyrotropy or birefringence, four-wave mixing of three light waves ω_j , k_j ($j = 1, 2, 3$) accompanied by generation of a new harmonic at the frequency $\omega_1 + \omega_2 - \omega_3$ and the wave vector $k_1 + k_2 - k_3$. Degenerate four-wave mixing is a particular case of the latter process, where two beams with the coinciding frequencies and different propagation directions, $k_1 \neq k_2$, interact and induce a new spatial harmonic $2k_1 - k_2$ or $2k_2 - k_1$.

Pump-probe spectroscopy

In a widely-used two-pulse optical excitation of a solid, the first pulse (pump) stimulates the system from its equilibrium state. The excited state exhibits a time scale of picosecond or femtosecond for relaxation dynamics. Then a probe (second laser pulse) examines the system at varying temporal delays in the excited state. This nonlinear optical method of study of excited state dynamics is termed as pump-probe spectroscopy. The technique is applicable to different classes of solids, semiconductors and dielectrics, ferro- and antiferromagnetics, ferroelectrics and multiferroics as well as the nanomaterials such as quantum wells, nanowires, nanotubes, quantum dots, graphene etc. First we describe this technique applied to study spin or magnetization dynamics.

Spin Faraday and Kerr rotation

At present the optical orientation of electron spins described in Section “Optical orientation of electron spins” is mostly studied in the polarized pump-probe measurements. A first short intense pulse of circularly polarized light generates the nonequilibrium spin-oriented electrons and holes and creates a macroscopic spin polarization. In accordance to Section “Magnetic field influence”, in a constant transverse magnetic field, $B^{(0)}$, applied to the sample, the macroscopic polarization starts to precess around the field direction with the Larmor frequency (the so-called spin quantum beats). The spin can also precess in time at zero magnetic field due to the splitting of spin sublevels governed by the Dresselhaus bulk and Rashba structural inversion asymmetries. The optically created polarization, its precession and transport can be probed by short pulses of linearly polarized light via rotation of their polarization plane after the propagation through the photoexcited medium (spin Faraday effect) or reflection from this medium (spin Kerr effect). The probe pulses of linearly polarized light show a remarkable sensitivity to the practically instant population of electron spin sublevels.

The pump-probe spin-dependent rotation techniques are especially useful for manipulation and measurement of electron spin polarization in singly charged quantum dots due to a very long coherence time of resident-electron spins.

The spin Faraday or Kerr rotation is so sensitive that it allows to monitor equilibrium randomly-varying spin fluctuations by means of the linearly polarized continuous wave probe without any pump ray. This kind of spin noise technique is especially well suited to study slow spin relaxation in semiconductor nanostructures.

Pump-probe micro-spectroscopy

An important type of the technique is the pump-probe micro-spectroscopy which combines the near-diffraction-limited spatial resolution with femtosecond temporal resolution. The pump-probe microscope is capable of exciting a sample in one location and probing the pump-induced change in another location, e.g. a change in absorption or spin Kerr rotation. It enables direct imaging of transport phenomena such as free carrier charge and spin diffusion, exciton migration and plasmon propagation in solids. At close-to-zero delay, the probe pulse is affected only within the area of the pump excitation. At longer delay times, changes in the pump-probe signal extend, due to the transportation, far from the excitation spot.

Conclusion

The analysis of optical properties of semiconductors and dielectrics reveals our understanding of the light-matter interaction. In the present chapter we have considered the propagation of electromagnetic waves in solids as described by Maxwell’s macroscopic equations and the dielectric tensor. The latter is a function of light frequency and may also depend on the external or internal parameters leading to birefringence, magneto- and electro-optical effects, piezospectroscopy and the spatial dispersion, in particular, natural optical activity. The optical reflection, transmission and absorption are the standard methods of noninvasive characterization of materials. An important attention is attracted to the excitonic effects in semiconductors and semiconductor nanostructures (Wannier–Mott excitons) and molecular crystals (Frenkel excitons), fine structure of exciton levels. Mixing of a photon and a quasi-particle excitation results in formation of hybrid excitations, e.g., optical-phonon and exciton polaritons. We have outlined the well-established optical materials, such as dielectrics activated by impurities, e.g., active species in solid lasers and novel materials, metamaterials, resonant microcavities and photonic crystals. The secondary light emission is presented by polarized photoluminescence spectroscopy due to optical orientation of free-carrier spins. The nonlinear optics is represented by second harmonic generation and pump-probe spectroscopy. Novel trends are illustrated by single-photon sources and two-photon entanglement.

Abstract

Traditional and newly developed aspects of polarizability are described from the viewpoint of micro and macroscopic responses, local and non-local behavior, and their roles in electromagnetic (EM) responses. A generalization of polarizability is given as a single susceptibility covering electric, magnetic and chiral polarizations for isolated charged particles in transversal and longitudinal external EM fields. It gives the first-principles expression of chiral susceptibility, absent in the literature. The argument is based on the minimal coupling Lagrangian for charged particles in an EM field, and the response is guaranteed to be gauge invariant.

Traditional aspects

Electromagnetic (EM) field in the presence of a matter is described by the Maxwell equations with source terms of charge and current densities. The current density consists of $\partial \mathbf{P} / \partial t$ and $\nabla \times \mathbf{M}$, where $\mathbf{P}$ and $\mathbf{M}$ are electric and magnetic polarization, respectively. In the usual definition of polarizability only $\mathbf{P}$ is considered as the induced change of matter. In this section we follow this line of argument, and a more general one is given in Sec“Generalization of polarizability”.

[☆]Change History: October 2022. K Cho updated some part of section Generalization of polarizability.

The induced charge and current densities in the Maxwell equations should be determined from the self-consistent motions of matter and EM field. Today this can be done with quantum mechanics and a computer if necessary. Historically, a phenomenology has been used with the Maxwell equations, where constant value is assigned to the polarizability of each part of material as a parameter. It describes the induced polarization as a function of incident EM field, which allows to find the solution in each part of material with a same polarizability. Then, these solutions are connected with one another via the so-called Maxwell boundary conditions, i.e., the continuity of the normal or tangential components of EM field across a surface/interface (Jackson, 1998). This determines the response of matter to an incident EM field uniquely. Another naming “electric susceptibility” is also used for polarizability.

Polarizability can be calculated quantum mechanically by evaluating the induced polarization from $\text{Trace} \{ \rho_M \hat{P} \}$ in the presence of incident EM field, where ρ_M is the density matrix of the matter and $\hat{P}$ the polarization (or dipole density) operator. The result is called constitutive equation, which gives $\hat{P}$ as a power series expansion of EM field. Solving the Maxwell and constitutive equations simultaneously, we obtain the solution on a higher theoretical level than phenomenology.

Macroscopic polarizability

In macroscopic (local) theory of optical response, the polarizability relates a source electric field $E(\mathbf{r}, \omega)$ with the induced polarization $P(\mathbf{r}, \omega)$ of a matter as

$$\begin{aligned} P_\xi(\mathbf{r}, \omega) = & \varepsilon_0 \sum_\eta \bar{\chi}_{\xi, \eta}^{(1)}(\omega) E_\eta(\mathbf{r}, \omega) \\ & + \varepsilon_0 \sum_\eta \sum_\zeta \bar{\chi}_{\xi, \eta, \zeta}^{(2)}(\omega', \omega'') E_\eta(\mathbf{r}, \omega') E_\zeta(\mathbf{r}, \omega'') \Big|_{\omega' + \omega'' = \omega} \\ & + \dots \end{aligned} \quad (1)$$

where $\mathbf{r}$ and ω are position and frequency, respectively, (ξ, η) stand for the Cartesian coordinates, ε_0 the dielectric constant of vacuum, and $\bar{\chi}^{(N)}$ the polarizability of the N -th order nonlinear process. The coefficients $\{\bar{\chi}^{(N)}\}$ are tensor quantities because they give relationships between different vectors. $N = 1$ corresponds to linear process, and $N = 2, 3$, etc. to the nonlinear ones of the second-, third-order etc., respectively. This equation is called local in the sense that P and E at the same position are related. This should be contrasted with the microscopic nonlocal polarizability to be mentioned later.

These polarizabilities are allowed to have dependence, not on position, but on frequencies, within the framework of macroscopic response. A typical model with the frequency dependence is the so-called Lorentz oscillator model, which regards matter as an assembly of charged oscillators. Using a model of ‘damped harmonic oscillator in a vibrating force’ of classical mechanics, one can derive a simple expression of the frequency dependence of, e.g., linear polarizability as

$$\bar{\chi}^{(1)}(\omega) = \frac{N_0 Q^2}{M} \frac{1}{\omega_0^2 - \omega^2 - i\gamma\omega}, \quad (2)$$

where N_0 , Q , M , ω_0 , γ are the number density, charge, mass, resonant frequency, and the damping parameter, respectively, of the oscillators. Appropriate choice of these parameters for a given material allows us to describe the ω -dependence of response spectrum. The ω -dependence of $\bar{\chi}^{(1)}(\omega)$ is, apart from the parameter values, essentially same as the quantum mechanical result, as shown below. For a given material, there can be many different types of oscillators with different parameters.

The frequency ω_0 corresponds to the excitation energy (divided by $\hbar$) of the matter, so that there are infinitely many of them in general. For an optical process near a resonance, it is often the case that this particular one is treated as a Lorentz oscillator explicitly and all the others as a frequency independent background medium. Thus the $\bar{\chi}^{(1)}$ to be used in such a treatment is the resonant term (2) plus a constant background polarizability χ_b . The idea of introducing background medium is a kind of “wisdom” to circumvent the tedious complexity arising from the infinite number of freedom.

Microscopic polarizability

Polarizabilities can be calculated quantum mechanically by evaluating the induced polarization as a functional of source electric field via a time dependent perturbation calculation with respect to the matter-EM field interaction. If one does it properly, we obtain microscopic constitutive equation, i.e., a nonlocal relationship between P and E as

$$\begin{aligned} P_\xi(\mathbf{r}, \omega) = & \varepsilon_0 \sum_\eta \int d\mathbf{r}' \bar{\chi}_{\xi, \eta}^{(1)}(\mathbf{r}, \mathbf{r}', \omega) E_\eta(\mathbf{r}', \omega) \\ & + \varepsilon_0 \sum_\eta \sum_\zeta \int d\mathbf{r}' \int d\mathbf{r}'' \bar{\chi}_{\xi, \eta, \zeta}^{(2)}(\mathbf{r}, \mathbf{r}', \mathbf{r}''; \omega', \omega'') E_\eta(\mathbf{r}', \omega') E_\zeta(\mathbf{r}'', \omega'') \Big|_{\omega' + \omega'' = \omega} \\ & + \dots \end{aligned} \quad (3)$$

The integral kernels $\chi^{(1)}$ and $\chi^{(n)}$ ($n = 2, 3, \dots$) are the nonlocal polarizabilities of the linear and the n -th order nonlinear processes, respectively. The quantum mechanical expressions of, for example, the linear susceptibility at absolute zero Kelvin is given as (D’Andrea and Del Sole, 1982)

$$\chi_{\xi, \eta}^{(1)}(\mathbf{r}, \mathbf{r}', \omega) = \sum_v \left\{ \frac{\langle 0 | \hat{P}_\xi(\mathbf{r}) | v \rangle \langle v | \hat{P}_\eta(\mathbf{r}') | 0 \rangle}{E_v - E_0 - \hbar\omega - i\gamma} + \frac{\langle 0 | \hat{P}_\eta(\mathbf{r}') | v \rangle \langle v | \hat{P}_\xi(\mathbf{r}) | 0 \rangle}{E_v - E_0 + \hbar\omega + i\gamma} \right\}, \quad (4)$$

where ν runs over all the excited states of the matter from the ground state $|0\rangle$. The parameter γ is, for idealized systems, a positive infinitesimal (0^+) representing the adiabatic switching of light-matter interaction, and for realistic systems, it is the self-energy of the excitation $E_\nu - E_0$, caused by nonradiative scattering, and is often approximated as a ω -independent phenomenological parameter. The effect of radiative damping appears automatically on solving the coupled equations for E and P , as shown later. Therefore it should not be included in γ to avoid double counting of the interaction. The introduction of the background polarizability can be done similarly as before.

Microscopic nonlocal response

The nonlocal relationship between the polarization and electric field in the above expression is due to the coherence of the relevant wave functions and also to the intention to consider the spatial structure microscopically down to the subatomic scale. Macroscopic response theory is derived from microscopic one via long wavelength approximation (LWA), and therefore its local character is meant, not on microscopic, but on macroscopic scale.

Nonlocality becomes important when we consider resonant EM response, since the resonant condition picks up a particular excited state with an enhanced amplitude. This leads to the dominance of the polarization structure due to this particular excitation. Therefore, the validity condition of LWA in this situation is that the resonant wavelength is much larger than the spatial extension of the polarization pattern. Atomic excitations are the examples of valid LWA, so that an excitation is safely described by excitation energy and transition dipole moment, which is the first moment of transition dipole density. Namely, the nonlocal polarizability (4) can be reduced to a local one (2) through the replacement

$$\hbar\omega_0 \rightarrow E_{\nu 0}, \quad \frac{Q^2}{M} \rightarrow \frac{2E_{\nu 0}}{\hbar} |M_{\nu 0}|^2 \quad (5)$$

where $M_{\nu 0}$ is the electric dipole moment of the transition with the excitation energy $E_{\nu 0}$.

The typical example of invalid LWA is the problem of additional boundary condition (ABC) for polariton, because the spatial extension of polariton can never be smaller than resonant wavelength. The ABC problem of polariton has a long history of conflicting arguments since its proposal (Pekar, 1957), because it was regarded as a problem of macroscopic EM response. The right answer was found when this problem is of a microscopic EM response, i.e., one needs to solve Maxwell equation with the polarizability explicitly containing material boundary. This way of solution was shown to be feasible because of the separable nature of polarizability in general (D'Andrea and Del Sole, 1982; Zeyher et al., 1972), which can further be extended to ABC-free theory of polariton, and finally, to a more general scheme of nonlocal EM response theory (Cho, 2003). The main stage of the nonlocal response theory is the nanostructured materials, which show the EM response dependent on the size, shape and internal structure of samples. This is a reflection of their size quantized energy levels and the corresponding spatial structure of excited states.

The main difference between the macroscopic and microscopic response theories lies in whether or not the boundary condition for EM field is required. The reason why it is required in the macroscopic theory is that a medium is defined by position-independent polarizabilities surrounded by surfaces/interfaces, so that the boundary problem exists, not for materials, but for EM field. In the case of microscopic response, on the other hand, the information about sample boundary is included in polarizability so that there is no need of boundary problem for EM field at the surface/interface of a sample.

Determination of microscopic response

The solution for microscopic EM response is obtained by solving Maxwell and microscopic constitutive equations simultaneously. From the Maxwell equation with polarization as a source term, the electric field produced by the polarization can be written as (Cho, 2003)

$$E_\xi(\mathbf{r}, \omega) = E_{0,\xi}(\mathbf{r}, \omega) + \sum_\eta \int d\mathbf{r}' G_{\xi,\eta}(\mathbf{r}, \mathbf{r}', \omega) P_\eta(\mathbf{r}', \omega) \quad (6)$$

where E_0 is an incident field, and $G_{\xi,\eta}(\mathbf{r}, \mathbf{r}', \omega)$ is the (ξ, η) -tensor component of the radiation Green's function of vacuum, which satisfies the differential equation

$$\left(\nabla \times \nabla \times + \frac{\omega^2}{c^2} \right) \mathbf{G}(\mathbf{r}, \mathbf{r}', \omega) = \mathbf{1} \delta(\mathbf{r} - \mathbf{r}'). \quad (7)$$

The self-consistent solution of the EM field and the induced polarization is obtained by solving (3) and (6) simultaneously. For this purpose one introduces the new variables

$$F_{\mu\nu}(\omega) = \int d\mathbf{r} E(\mathbf{r}, \omega) \cdot \langle \mu | \hat{\mathbf{P}}(\mathbf{r}) | \nu \rangle. \quad (8)$$

The induced polarization $\mathbf{P}$ is written as a polynomial series of these variables, which together with (6) gives E also in a polynomial series of these $\{F\}$'s. Substituting the latter into (8), one obtains a set of polynomial equations to determine $\{F\}$'s. For a given order of optical process, linear or N-th order nonlinear one, the solution of these simultaneous polynomial equations determines the response for a given incident field E_0 .

For linear process, one has a set of linear equations for $\{F\}$'s. The condition for the existence of nontrivial solution in the absence of incident field E_0 is given as the vanishing of the determinant of the coefficient matrix $\det |\mathbf{S}| = 0$. This is the equation for the eigenmode of the light-matter coupled system. In the rotating wave approximation, where only the first term on the right hand side of (4) is retained, we have

$$S_{\mu\nu} = (E_\mu - \hbar\omega)\delta_{\mu\nu} + \mathcal{A}_{\mu 0,0\nu}(\omega). \quad (9)$$

The quantity $\mathcal{A}_{\mu 0,0\nu}(\omega)$ represents the interaction energy between the induced polarization components via transverse EM field (vacuum photons) with frequency ω as

$$\mathcal{A}_{\mu 0,0\nu}(\omega) = - \int d\mathbf{r} \int d\mathbf{r}' < \mu | \hat{\mathbf{P}}(\mathbf{r}) | 0 > \cdot \mathbf{G}(\mathbf{r}, \mathbf{r}', \omega) \cdot < 0 | \hat{\mathbf{P}}(\mathbf{r}) | \nu >, \quad (10)$$

which is a complex quantity. Since the eigenmode of the coupled system gives the resonant structure in optical spectrum, the real and imaginary parts of $\mathcal{A}_{\mu 0,0\nu}(\omega)$ represent of the radiative shift and width of the matter excitation energy with frequency dependence. In this sense, a matter is an assembly of oscillating dipole densities with finite spatial extension and radiative shift and width, which can be defined precisely on a quantum mechanical basis. In atomic systems, this radiative correction is very small, but in nanoscale systems and in the bulk, this correction can be comparable to or even exceeds the level spacing of matter. For example, the difference between the dispersion curves of an exciton and polariton is just the radiative shift defined above. More examples of the radiative correction in nonlocal situations can be found in Sections 4 and 5 of [Cho, \(2003\)](#) ([Ishihara and Cho, 2023](#)).

Polariton dispersion equation

Polarizability plays an essential role to determine the eigenmodes of light-matter coupled systems. Among various examples of such an eigenmode, let us take the case of an exciton in a three-dimensional crystal. The eigenmode of the coupled light-matter system is an exciton-polariton, whose dispersion equation is obtained from the coupled linear equations

$$0 = \mathbf{k} \times \mathbf{k} \times \mathbf{E}(\mathbf{k}, \omega) + \frac{\omega^2}{c^2} (1 + \chi_B^{(1)}) \mathbf{E}(\mathbf{k}, \omega). \quad (11)$$

If symmetry allows pure T modes, this leads to the polariton dispersion equation $1 + \chi_B^{(1)} = (ck/\omega)^2$.

A more general equation for matter excitation coupled with EM field is the eigenmode equation $\det |\mathbf{S}| = 0$ mentioned in connection with (9). This requests the finite amplitudes of matter polarization and response field in the absence of external excitation, which may appropriately be called 'self-sustaining mode'. This applies not only to polaritons but also to any matter excitation with radiative correction. Furthermore, it can be extended to X-ray scattering, since the Umklapp effect can easily be included through the Fourier components of the induced microscopic polarization. This can be used for the X ray propagation in a crystal in the dynamical scattering regime ([Batterman and Cole, 1964](#)). The generalized dispersion equation has the form

$$0 = \det \left| \{ |\mathbf{k} + \mathbf{g}|^2 - q^2 \} \delta_{i,j} \delta_{\mathbf{g},\mathbf{g}'} - q^2 \hat{\mathbf{e}}_i(\mathbf{k} + \mathbf{g}) \cdot \chi_A^{(1)} \cdot \hat{\mathbf{e}}_j(\mathbf{k} + \mathbf{g}') \right|, \quad (12)$$

where $q = \omega/c$, $\{\mathbf{g}\}$ reciprocal lattice vectors, and $\{\hat{\mathbf{e}}_i(\mathbf{k} + \mathbf{g}); i = 1, 2\}$ are the mutually orthogonal unit vectors perpendicular to $\mathbf{k} + \mathbf{g}$. The polarizability $\chi_A^{(1)}$ is the $\{\mathbf{k} + \mathbf{g}, \mathbf{k} + \mathbf{g}'\}$ Fourier components of the polarizability of the scheme [A] mentioned before, which can contain all the resonances of the crystal.

If one neglects the matrix elements with suffices of finite reciprocal lattice vectors in (12), the reduced equation can be shown to be equivalent to the general dispersion equation obtained from (11), which allows the LT mixed mode polaritons.

From the fact that the generalized dispersion Eq. (12) contains the effect of both resonance and Bragg scattering, it can be used in diverse situations such as polaritons, X-ray dynamical scattering, and photonic crystal ([Inoue and Ohtaka, 2004](#)) in extended frameworks.

Oscillator strength and its size dependence

There is a quantity closely related with polarizability, namely, oscillator strength, which characterizes the coupling strength of a matter excitation with EM field. It is defined as

$$f_{v0} = \frac{2mE_{v0}}{\hbar^2 e^2} |M_{v0}|^2 \cos^2 \theta \quad (13)$$

where θ is the angle between the transition dipole moment vector and light polarization direction. This factor is proportional to the numerator of the resonant polarizability in (2), as shown in (5). This is a useful concept within LWA. In nanoscale systems, there can be a quantum state extending over the whole sample region, which may exhibits size linear enhancement of its oscillator strength. As sample size approaches the wavelength of resonant light from below, this size enhancement tends to saturate. This enhancement is not reflected on the linear polarizability, because induced (linear or nonlinear) polarization is defined as the induced dipole moment per volume. Following this definition, however, it has an effect on nonlinear polarizability. For example, $\chi^{(3)}$ for macroscopic response can exhibits size-linear enhancement, which is of course valid only in LWA.

Beyond the size region of LWA, oscillator strength is no more an appropriate measure of the coupling strength. As a more general measure, one can use the radiative width of each excitation, i.e., the imaginary part of $A_{v0, 0v}$ defined in (10). This quantity can be used irrespective of LWA. Since it is proportional to $|M_{v0}|^2$, i.e., to oscillator strength, in LWA, it can be used more generally than oscillator strength. The size dependence of radiative width is very sensitive to the spatial structure of size quantized excitations. Following the size evolution of a given excitation, one can observe, not only the size-linear enhancement in LWA regime, but also size-resonant enhancement beyond LWA. For each type of excitations, there is a characteristic size where the coupling with EM field becomes maximal. Examples for excitons in a slab can be found in Chapter 00176 (Ishihara and Cho, 2023).

If the coupling with EM field becomes very large as, e.g., in a resonant Bragg reflector consisting of regular arrays of quantum wells (QW's) with electronic resonances, where the resonant light satisfies the Bragg condition, it is no more appropriate to neglect the frequency dependence of radiative correction, (10). In this situation, the coupling of light-matter system is so strong that it is no more valid to regard its eigenmode as a matter oscillator corrected with radiative shift and width. In the above example, there is formation of photonic bands with a gap mode branch by increasing the number of QW's (Ikawa and Cho, 2002).

Different definitions of polarizability

The definition of polarizability depends on what the polarizing field is. When a light is incident on an isolated matter, the light polarizes the matter, and the induced oscillating polarization emits EM field with the same frequency, and this EM field polarizes the matter further, and so on. Even if a polarizing field is purely transverse (T), the induced polarization can generally contain both longitudinal (L) and T components. Both of them act as the course term in the Maxwell equations, leading to the Maxwell field with both T and L components. Since the L component of the Maxwell field is caused by the induced charge density, the interaction of this L field with the matter polarization is a part of the Coulomb interaction among the charged particles, i.e., the Coulomb interaction among the induced charge densities H_{cc} . Electron-hole exchange interaction can also be rewritten in such a form. The LT splitting of polarization waves in a crystal may be expressed as a part of matter excitation energy, but it could also be ascribed to the interaction energy of a polarization wave with induced depolarization field.

There are two points of view about the treatment of H_{cc} , i.e., as a part of [A] matter Hamiltonian, or [B] the interaction between matter and external field (Cho, 1999). For each viewpoint, there is a suitable set of 'matter Hamiltonian, external EM field, the interaction between them, and polarizability'. Namely, H_A should contain the full Coulomb interaction, while H_{cc} , a part of the Coulomb interaction, should be excluded from H_B , i.e., $H_B = H_A - H_{cc}$. The fields inducing the polarization should be chosen as the full Maxwell field E in scheme [B], while it is only the T component of E in scheme [A]. The linear polarizability in each case is given in the same form as (4), but the energy eigenvalues and the matrix elements of polarization operator are different because of the difference in the matter Hamiltonian. One can show the equivalence of these two points of view, at least for linear response. Depending on the problem to be considered, one can choose either of them with proper consideration of the matter Hamiltonian to be used.

As a simple example, let us consider the electronic excitations in a crystal, i.e., the case where wave vector is a good quantum number. Neglecting the effect of finite reciprocal wave vectors (Umklapp processes), we can treat $\chi^{(1)}$ as a function of $\mathbf{r} - \mathbf{r}'$ alone. Its Fourier transform $\chi^{(1)}(\mathbf{k}, \omega)$ has a different relationship, depending on the scheme [A] and [B], with dielectric function defined as $D(\mathbf{k}, \omega) = \varepsilon_0 \varepsilon(\mathbf{k}, \omega) E(\mathbf{k}, \omega)$. From $\nabla \cdot D = 0$ and $P = \varepsilon_0 \chi_A^{(1)} E^{(T)} = \varepsilon_0 \chi_B^{(1)} E$, one can derive

$$\varepsilon = 1 + \chi_B^{(1)}, \quad (14)$$

and

$$\chi_B^{(1)} = \chi_A^{(1)} + \chi_A^{(1)} \cdot \frac{\mathbf{k}\mathbf{k}}{k^2} \cdot \chi_B^{(1)}. \quad (15)$$

The excitation energies of the matter Hamiltonian appear as the poles of $\chi^{(1)}$. Therefore all the matter excitation energies of both T and L characters in the scheme [A] appear as the poles of $\chi_A^{(1)}$. The matter Hamiltonian in the scheme [B] does not contain H_{cc} , so that its T and L levels are degenerate. The interaction with the external L field lifts the degeneracy and gives an additional energy to the L state alone, which finally leads to the same resonant positions of the T and L levels of the light-matter coupled system. This situation in the scheme [B] is reflected in the above relationship, namely, the L mode excitations appear as the zeros of the dielectric function $\varepsilon = 1 + \chi_B^{(1)}$, and the T mode excitations as the poles of $\chi_B^{(1)}$.

The above relationship between $\chi_A^{(1)}$ and $\chi_B^{(1)}$ can be generalized to the case without translational symmetry. If we denote the $(\mathbf{k}, \mathbf{k}')$ -Fourier components of the linear polarizabilities as $\chi_A^{(1)}(\mathbf{k}, \mathbf{k}'; \omega)$ and $\chi_B^{(1)}(\mathbf{k}, \mathbf{k}'; \omega)$, respectively, their relationship is generally given as

$$\chi_B^{(1)}(\mathbf{k}, \mathbf{k}') = \chi_A^{(1)}(\mathbf{k}, \mathbf{k}') + \frac{1}{2\pi^2} \int d\mathbf{q} \chi_A^{(1)}(\mathbf{k}, \mathbf{q}) \cdot \frac{\mathbf{q}\mathbf{q}}{q^2} \cdot \chi_B^{(1)}(\mathbf{q}, \mathbf{k}'), \quad (16)$$

with the omission of the common variable ω .

Cancellation problem in nonlinear polarizabilities

For the calculation of polarizabilities in (3), we use the time dependent perturbation theory with light-matter interaction

$$H_{\text{int}} = - \int d\mathbf{r} \hat{\mathbf{P}}(\mathbf{r}) \cdot \mathbf{E}(\mathbf{r}, t) \quad (17)$$

as the perturbation Hamiltonian. The n -th order nonlinear polarizability is expressed as the n -fold time integral of the n -fold commutator of polarization operators in interaction representation. For the explicit calculation, one expands the n -fold commutator into the sum of various products of the polarization operators, and carry out the time integrations. When one sums up these integrated terms, there occurs partial or total cancellation among them for n larger than or equal to 2. A typical example is the polarization made of pure Bosons such as harmonic oscillators. In this case, the innermost commutator of two polarization operators in the interaction representation at different times becomes a c -number, so that its commutator with another operator turns out to be zero. This means that all the nonlinear polarizabilities should be zero for this model. However, each of the contributions from the expanded terms of the n -fold commutator is generally nonvanishing, which means that the complete cancellation occurs in summing up these expanded terms. For general cases of light-matter interaction, matter excitations are not pure Bosons, and there is interaction among them, which leads to finite nonlinear polarizability. But there always exists a partial cancellation in summing up the expanded terms.

This feature is important when one considers the size enhancement of nonlinear polarizabilities for a nanoscale matter. As we mentioned above, this enhancement tends to saturate as sample size grows to be comparable to the resonant wavelength. However, each of the expanded terms of the n -fold commutator is kept enhanced also beyond LWA. The saturation occurs only through the cancellation among such terms. This means that beyond LWA the leading order terms are cancelled out, leaving the next order terms as a finite contribution (Cho, 2003). Therefore, it is essential to make a very careful treatment of cancellation in the calculation of nonlinear polarizabilities. Otherwise, one would be left with a large error in their values.

Generalization of polarizability

Single susceptibility for three different polarizations

Polarizability is a quantity describing one particular aspect of EM response of matter, i.e. the electric polarization. Though it is in many cases a central importance, there are other type of EM responses, such as magnetic and chiral polarizations. In most cases, they are treated separately as if they are independent from one another. However, they obviously cannot be independent, if we consider the number of freedom of the cause (EM field) and the result (matter polarization) in general. Actually it is three for both of them, i.e., for any choice of EM variables from E , B , A , ϕ there are only three independent components, and the use of current density $\mathbf{J}$ is general enough for the induced change of matter. The linear relation between 2 three-component vectors is represented by a 3×3 tensor. Since current density contains electric and magnetic polarizations as $\mathbf{J} = \partial \mathbf{P} / \partial t + \nabla \times \mathbf{M}$, the 3×3 tensor should contain electric and magnetic susceptibilities, and, furthermore, chiral susceptibility in lower symmetry case where electric and magnetic polarizations are mixed.

This argument is closely related with EM response theory with minimal number of variables. This should apply to any level of response theories from quantum electrodynamics (QED) to micro- and macro- scopic semiclassical theories. These levels of response theories are mutually related via certain approximations, and form a single hierarchy with the rigorous QED at the top. In the hierarchy, macroscopic semiclassical theory is peculiar in the sense that it appeared in early days before quantum mechanics and relativity theory were born. Because of this historical background, there have been various ways of arguments based on empirical knowledge, making its logical position in the hierarchy difficult to see. After the first edition of this chapter, the author developed a first-principles scheme for the derivation of macroscopic Maxwell equations (Cho, 2010, 2018). The logical step from micro- to macroscopic theory is the application of LWA to the general form of microscopic constitutive equation. The resulting expression of the macroscopic single susceptibility is shown to be rewritten reversibly into separate forms of electric, magnetic and chiral susceptibilities. This includes the quantum mechanical expression of chiral susceptibility, which is absent in the literature.

In the following, we give some details of the formulation how to prepare the base of minimal number of necessary variables for general case of EM response, which was developed in Cho (2018).

Basics of single susceptibility theory

The formulation is based on the minimal coupling Lagrangian for interacting system of charged particles and EM field as

$$\mathcal{L} = \sum_{\ell} \frac{1}{2} m v_{\ell}^2 + \int d\mathbf{r} \{ -\rho \phi + \mathbf{J} \cdot \mathbf{A} \} + \frac{\epsilon_0}{2} \int d\mathbf{r} \left\{ \left(\frac{\partial \mathbf{A}}{\partial t} + \nabla \phi \right)^2 - c^2 (\nabla \times \mathbf{A})^2 \right\}. \quad (18)$$

where ℓ is particle index, ρ charge density, and ϕ , $\mathbf{A}$ scalar and vector potential, respectively. As a general framework of EM response, we consider an isolated system of charged particles interacting with an external EM field with transverse (T) and longitudinal (L) components. The external EM field is a fixed quantity playing the role of source field inducing current density.

The number of variables for EM field in this Lagrangian is redundant, because the least necessary number of its components is three, while vector and scalar potentials provide four. In order to reduce the number of variables, we carry out a variable transformation to eliminate scalar potential by using the Lagrange equation for ϕ , i.e., Gauss law. This does not change the Lagrange equations of all the other variables because the generalized velocity for ϕ is missing in $\mathcal{L}$ (Cohen-Tannoudji et al., 1989). The transformed Lagrangian turns out to be a sum of gauge independent term $\mathcal{L}'$ and gauge dependent term $\mathcal{L}''$, as

$$\mathcal{L}' = \sum_{\ell} \frac{1}{2} m_{\ell} v_{\ell}^2 - U_{\text{Ct}} + \int d\mathbf{r} \mathbf{J}_{\text{T}} \cdot \mathbf{A}_{\text{T}} + \frac{\epsilon_0}{2} \int d\mathbf{r} \left\{ \left(\frac{\partial \mathbf{A}_{\text{T}}}{\partial t} \right)^2 - (\nabla \times \mathbf{A}_{\text{T}})^2 \right\} \quad (19)$$

$$\mathcal{L}'' = - \frac{d}{dt} \int d\mathbf{r} \mathbf{P}_{\text{L}} \cdot \mathbf{A}_{\text{L}} \quad (20)$$

where U_{Ct} is the Coulomb potential among all the internal and external charged particles, obtained from the self-energy of longitudinal electric field by the help of Gauss law $\nabla \cdot \mathbf{E}_{\text{L}} = \rho/\epsilon_0$. The suffices T and L are for the transverse and longitudinal components, respectively, and $\mathbf{J}_{\text{L}} = \partial \mathbf{P}_{\text{L}}/\partial t$ is noted. $\mathbf{J}_{\text{T}}$ in the third term can be written as $\mathbf{J}$, since the additional contribution of $\mathbf{J}_{\text{L}}$ vanishes. Being the total time derivative, $\mathcal{L}''$ does not contribute to the least action principle, and can be dropped. The remaining Lagrangian $\mathcal{L}'$ is that of Coulomb gauge. This means that the Lagrangian in arbitrary gauge can always be replaced by that of Coulomb gauge. It should be noted that this result is obtained, not by choosing a gauge, but by using a more general rule of the least action principle.

The part of U_{Ct} representing the interaction between external and internal charges can be rewritten as 'the interaction of external L field $\mathbf{E}_{\text{extL}}$ with the polarization $\mathbf{P}$ due to internal charge density ρ' ($-\nabla \phi_{\text{ext}} = \mathbf{E}_{\text{extL}}$, $\nabla \cdot \mathbf{P} = -\rho$), or 'the potential energy of ρ in the external potential ϕ_{ext} '. The remaining part, U_{C} , represents the Coulomb interaction among internal charges alone. The T field $\mathbf{A}_{\text{T}}$ consists of the sum of external and internal (induced) components.

From $\mathcal{L}'$ we get Hamiltonian via standard procedure, which is appropriate for dealing with nonrelativistic systems of spinless particles in an EM field. In order to extend the range of problems to spin related ones, we add spin Zeeman interaction

$$\mathcal{H}_{\text{SZ}} = - \int d\mathbf{r} \mathbf{M}_{\text{s}}(\mathbf{r}) \cdot \mathbf{B}(\mathbf{r}) = - \int d\mathbf{r} \mathbf{J}_{\text{s}}(\mathbf{r}) \cdot \mathbf{A}(\mathbf{r}), \quad (21)$$

and spin-orbit interaction

$$\mathcal{H}_{\text{SO}} = \sum_{\ell} \frac{e_{\ell} \hbar}{4m_{\ell}^2 c^2} \mathbf{p}_{\ell} \cdot (\boldsymbol{\sigma}_{\ell} \times \mathbf{E}_{\text{L}}). \quad (22)$$

They are derived from Dirac equation for relativistic particles under the assumption of weakly relativistic condition (An additional remark about the relativistic correction will be made at the end of this section.). Note that $\mathcal{H}_{\text{SZ}}$ has the same form as the interaction between orbital current density and vector potential. This allows us to combine the spin and orbital parts into the total current density operator, as shown below. Altogether, the Hamiltonian becomes $\mathcal{H}_{\text{sc}} + \mathcal{H}_{\text{EM}}$, where

$$\mathcal{H}_{\text{sc}} = \sum_{\ell} \frac{1}{2m_{\ell}} \{ \mathbf{p}_{\ell} - e_{\ell} \mathbf{A}_{\text{T}}(\mathbf{r}_{\ell}) \}^2 + U_{\text{C}} - \int d\mathbf{r} \mathbf{P}(\mathbf{r}) \cdot \mathbf{E}_{\text{extL}}(\mathbf{r}) + \mathcal{H}_{\text{SZ}} + \mathcal{H}_{\text{SO}}, \quad (23)$$

$$\mathcal{H}_{\text{EM}} = \frac{1}{2} \int d\mathbf{r} \left\{ \epsilon_0 \left(\frac{\partial \mathbf{A}_{\text{T}}}{\partial t} \right)^2 + \frac{1}{\mu_0} (\nabla \times \mathbf{A}_{\text{T}})^2 \right\}. \quad (24)$$

where m_{ℓ} , e_{ℓ} , $\mathbf{r}_{\ell}$, $\mathbf{p}_{\ell}$ are the mass, charge, coordinate, and momentum, respectively, of the ℓ -th particle. Index ℓ is restricted to the internal particles alone. The vector potential $\mathbf{A}_{\text{T}}$ consists of internal and external (applied) components. This Hamiltonian provides a starting point for general class of problems about the EM response of interacting charged particles (neutral as a whole) and EM field. Polarizability and/or susceptibility appears in the semiclassical theory, where EM field is treated classically. This means that each mode of EM field, specified by frequency, polarization and propagation direction, is described by two dynamical variables, phase and amplitude (in contrast with the ensemble of photon states in QED). Thus, the theory of EM response is to determine the phases and amplitudes of EM field and induced current density of matter for a given initial condition (Though we stay in semiclassical regime, it is worth noting that this Hamiltonian can be used for QED in weakly relativistic condition just by quantizing $\mathbf{A}_{\text{T}}$).

As a standard example, we calculate linear susceptibility of matter at zero Kelvin for an incident EM field with T and L components. Solving Schrödinger (Pauli) equation $i\hbar(\partial\Psi/\partial t) = H_{\text{sc}}\Psi$, we have Ψ in the lowest order perturbation, and this allows us to calculate the expectation value of current density as $\langle \mathbf{J} \rangle(t) = \langle \Psi(t) | \mathbf{J} | \Psi(t) \rangle$. Its Fourier transform gives $\langle \mathbf{J} \rangle(\omega)$.

Separating $\mathcal{H}_{\text{sc}}$ into matter part $\mathcal{H}_{\text{m}}$ and linear and quadratic interaction terms $\mathcal{H}_{\text{int1}} + \mathcal{H}_{\text{int2}}$, we have

$$\mathcal{H}_{\text{m}} = \sum_{\ell} \frac{1}{2m_{\ell}} \mathbf{p}_{\ell}^2 + U_{\text{C}} + \mathcal{H}_{\text{SO}}, \quad (25)$$

$$\mathcal{H}_{\text{int}1} = - \int d\mathbf{r} \mathbf{I}(\mathbf{r}) \cdot \mathbf{A}_T(\mathbf{r}, t) - \int d\mathbf{r} \mathbf{P}_L(\mathbf{r}) \cdot \mathbf{E}_{\text{ext}L}(\mathbf{r}, t), \quad (26)$$

$$\mathcal{H}_{\text{int}2} = \frac{1}{2} \int d\mathbf{r} \hat{N}(\mathbf{r}) A_T(\mathbf{r})^2, \quad (27)$$

where

$$\hat{N}(\mathbf{r}) = \sum_{\ell} (e_{\ell}^2 / m_{\ell}) \delta(\mathbf{r}_{\ell} - \mathbf{r}), \quad (28)$$

$$\mathbf{I}(\mathbf{r}) = \mathbf{J}_0(\mathbf{r}) + \nabla \times \mathbf{M}_s(\mathbf{r}), \quad (29)$$

$$\mathbf{J}_0(\mathbf{r}) = \sum_{\ell} \frac{e_{\ell}}{2m_{\ell}} \{ \mathbf{p}_{\ell} \delta(\mathbf{r}_{\ell} - \mathbf{r}) + \delta(\mathbf{r}_{\ell} - \mathbf{r}) \mathbf{p}_{\ell} \}, \quad (30)$$

$$\mathbf{M}_s(\mathbf{r}) = \sum_{\ell} \frac{e_{\ell} \hbar}{m_{\ell}} \boldsymbol{\sigma}_{\ell} \delta(\mathbf{r}_{\ell} - \mathbf{r}). \quad (31)$$

The quadratic term $\mathcal{H}_{\text{int}2}$ is neglected for the argument of linear susceptibility. The total current density operator is $\mathbf{I}_t = \mathbf{I} - \hat{N}(\mathbf{r}) \mathbf{A}_T$. Taking the ω Fourier component of the expectation value of $\langle \Psi(t) | \mathbf{I}_t | \Psi(t) \rangle$, we obtain the induced current density as a linear functional of $\mathbf{A}_T$ and $\mathbf{E}_{\text{ext}L}$.

$$\bar{\mathbf{I}}_t(\mathbf{r}, \omega) = \int d\mathbf{r}' \chi_{\text{cd}}(\mathbf{r}, \mathbf{r}', \omega) \cdot \mathbf{A}_T(\mathbf{r}', \omega) + \int d\mathbf{r}' \chi_{\text{EL}}(\mathbf{r}, \mathbf{r}', \omega) \cdot \mathbf{E}_{\text{ext}L}(\mathbf{r}', \omega), \quad (32)$$

where χ_{cd} and χ_{EL} are the microscopic susceptibilities with respect to the source fields $\mathbf{A}_T$ and $\mathbf{E}_{\text{ext}L}$, respectively. Their quantum mechanical expressions are given as

$$\chi_{\text{cd}}(\mathbf{r}, \mathbf{r}', \omega) = - \langle 0 | \hat{N}(\mathbf{r}) | 0 \rangle + \sum [g_v(\omega) \mathbf{I}_{0v}(\mathbf{r}) \mathbf{I}_{v0}(\mathbf{r}') + h_v(\omega) \mathbf{I}_{v0}(\mathbf{r}) \mathbf{I}_{0v}(\mathbf{r}')], \quad (33)$$

$$\chi_{\text{EL}}(\mathbf{r}, \mathbf{r}', \omega) = \sum_v [g_v(\omega) \mathbf{I}_{0v}(\mathbf{r}) (\mathbf{P}_L)_{v0}(\mathbf{r}') + h_v(\omega) \mathbf{I}_{v0}(\mathbf{r}) (\mathbf{P}_L)_{0v}(\mathbf{r}')] \quad (34)$$

$$g_v(\omega) = 1/(E_{v0} - \hbar\omega - i0^+), h_v(\omega) = 1/(E_{v0} + \hbar\omega + i0^+), \quad (35)$$

where $\mathcal{H}_m | v \rangle = E_v | v \rangle$ and $E_{v0} = E_v - E_0$. By the help of the identity $\mathbf{I}_L = \partial \mathbf{P}_L / \partial t$, which leads to $\langle \mu | \mathbf{P}_L | v \rangle = -i(\hbar/E_{\mu v}) \langle \mu | \mathbf{I}_L | zv \rangle$, χ_{EL} can be rewritten, in terms of current density matrix elements, as

$$\chi_{\text{EL}}(\mathbf{r}, \mathbf{r}', \omega) = - \frac{i}{\omega} \sum_v [\bar{g}_v(\omega) \mathbf{I}_{0v}(\mathbf{r}) \mathbf{I}_{v0}^{(L)}(\mathbf{r}') + \bar{h}_v(\omega) \mathbf{I}_{v0}(\mathbf{r}) \mathbf{I}_{0v}^{(L)}(\mathbf{r}')] \quad (36)$$

where $\bar{g}_v(\omega) = g_v(\omega) - 1/E_{v0}$ and $\bar{h}_v(\omega) = h_v(\omega) - 1/E_{v0}$.

Both of the susceptibilities describe the nonlocal response, i.e., current density can be induced at positions different from those of incident field. The spatial extension of this nonlocality is determined by that of the relevant matter excited states given by $|0\rangle$ and $|v\rangle$. If this spatial extension is comparable to or larger than the wavelength of the EM field resonant to this excitation, we cannot use LWA. In that case, we have to calculate the EM response via proper consideration of nonlocality. Thereby, the separable character of the susceptibilities as integral kernel allow us to rewrite integral equations into simultaneous linear equations, which in many cases allows successful treatments beyond LWA (Cho, 2003).

Problems of our interest are resonant EM responses, where incident EM field is resonant with some excitations of matter. The contributions of resonant and off-resonant matter excitations to the susceptibility are treated differently. There are generally infinite number of off-resonant states, and their total contribution to induced current density would show mild dependence on spatial and ω variation in contrast to that of resonant states. Then, the contribution of off-resonant states to susceptibility may be replaced by some background constant without ω and spatial dependence, which alone can be treated as macroscopic response. It is the spatial extension of resonant states which determines whether the total response may be treated as macro- or microscopic response.

Derivation of macroscopic susceptibility

In order to carry out LWA in the microscopic constitutive equation, we make Fourier expansion of the corresponding current density matrix elements and keep the lower order terms of wave number components, which, together with the Maxwell equations in $\mathbf{k}$ representation, provides the fundamental equations of macroscopic response theory. For systems which allow LWA, this is the model-independent, logically acceptable way to derive macroscopic theory.

In this way, we can have a macroscopic EM response theory belonging to the lowest rank of the hierarchy of EM response theories, which consists of [a] relativistic QED and [b] weakly-relativistic QED, [c] semiclassical microscopic theory, and [d] semiclassical macroscopic theory, related through well-defined approximations. In the past arguments, the logical step from [c] to [d] was not quite clear, because of model dependent arguments and of the absence of examination of validity condition. Typical example is the ABC problem mentioned in Section “Microscopic nonlocal response”, which was first proposed for [d], but the right answer was found from [c].

Before showing the detailed form of LWA averaged susceptibility, it may be useful to consider the rewriting of the non-resonant term $\sim \langle 0|\hat{N}(\mathbf{r})|0\rangle$ in χ_{cd} . This term is the ground state charge density. Because of the weighting factor e_e^2/m_e , electrons dominate over heavier nuclei. In X-ray diffraction, it plays an essential role with its r -dependence reflecting the positions of nuclei of the matter. As averaged uniform charge density in LWA, it contributes to plasma frequency. For macroscopic EM response, we rewrite this term, to the lowest order $O(k^0)$, as

$$\langle 0|\hat{N}(\mathbf{r})|0\rangle = \langle 0|\left[J_{\mathbf{k}}^{(\xi)}, P_{-\mathbf{k}}^{(\eta)}\right]|0\rangle. \quad (37)$$

Further rewriting via $\langle \mu|\mathbf{P}_k|v\rangle = (-i/\omega_{\mu v})\langle \mu|\mathbf{J}_k|v\rangle$ allows to renormalize it into the form of resonant terms with g, h replaced by $\bar{g}, \bar{h}$. With this approximation, we have a neat expression of the macroscopic constitutive equation for general T and L source field

$$\bar{\mathbf{I}}_t(\mathbf{k}, \omega) = \chi_{\text{em}}(\mathbf{k}, \omega) \cdot \left\{ \mathbf{A}_T(\mathbf{k}, \omega) - \frac{i}{\omega} \mathbf{E}_{\text{extL}}(\mathbf{k}, \omega) \right\}, \quad (38)$$

where

$$\chi_{\text{em}}(\mathbf{k}, \omega) = V \sum_v [\bar{g}_v(\omega) \mathbf{I}_{0v}(\mathbf{k}) \mathbf{I}_{v0}(-\mathbf{k}) + \bar{h}_v(\omega) \mathbf{I}_{v0}(\mathbf{k}) \mathbf{I}_{0v}(-\mathbf{k})]. \quad (39)$$

The $\mathbf{k}$ Fourier component of matrix element is given as a power series of $\mathbf{k}$ as

$$\tilde{\mathbf{I}}_{\mu v}(\mathbf{k}) = \frac{\exp(-i\mathbf{k}\cdot\bar{\mathbf{r}})}{V} \left[\bar{\mathbf{J}}_{\mu v} - i\mathbf{k}\cdot\bar{\mathbf{Q}}_{\mu v}^{(e2)} + i\mathbf{k} \times \bar{\mathbf{M}}_{\mu v} + \dots \right], \quad (40)$$

in terms of the electric dipole (E1), electric quadrupole (E2) and magnetic dipole (M1) moments of transition matrix elements. V is the volume to define $\mathbf{k}$ via periodic boundary condition, and $\bar{\mathbf{r}}$ is the center coordinate to define moments for each transition $|0\rangle \leftrightarrow |v\rangle$. The zero-th order moment of $\mathbf{J}_0$ is the E1 moment

$$\bar{\mathbf{J}}_{\mu v} = \int d\mathbf{r} \langle \mu|\mathbf{J}_0(\mathbf{r})|v\rangle, \quad (41)$$

The $O(k^1)$ moment of $\mathbf{J}_0$ is the sum of the E2 moment $\bar{\mathbf{Q}}_{\mu v}^{(e2)}$ defined by

$$\mathbf{k}\cdot\bar{\mathbf{Q}}_{\mu v}^{(e2)} = \sum_{\ell} \frac{e_{\ell}}{2m_{\ell}} \int d\mathbf{r} [\langle \mu|(\mathbf{r}_{\ell} - \bar{\mathbf{r}})\mathbf{k}\cdot\mathbf{p}_{\ell}\delta(\mathbf{r}_{\ell} - \bar{\mathbf{r}}) + \delta(\mathbf{r}_{\ell} - \bar{\mathbf{r}})(\mathbf{r}_{\ell} - \bar{\mathbf{r}})\mathbf{k}\cdot\mathbf{p}_{\ell}|v\rangle] \quad (42)$$

and the orbital M1 moment

$$\bar{\mathbf{M}}_{\mu v}^{(\text{orb})} = \sum_{\ell} \frac{e_{\ell}}{2m_{\ell}} \int d\mathbf{r} [\langle \mu|\mathbf{L}_{\ell}(\bar{\mathbf{r}})\delta(\mathbf{r}_{\ell} - \bar{\mathbf{r}}) + \delta(\mathbf{r}_{\ell} - \bar{\mathbf{r}})\mathbf{L}_{\ell}(\bar{\mathbf{r}})|v\rangle] \quad (43)$$

where $\mathbf{L}_{\ell}(\bar{\mathbf{r}}) = (\mathbf{r}_{\ell} - \bar{\mathbf{r}}) \times \mathbf{p}_{\ell}$. The total M1 moment $\bar{\mathbf{M}}_{\mu v}$ in (40) is the sum of the orbital M1 moment and the spin M1 moment $\langle \mu|\mathbf{M}_s(\mathbf{r})|v\rangle$.

The macroscopic susceptibility χ_{em} includes all the effects of electric, magnetic, and chiral polarizations, i.e., $O(k^0)$ terms represent the E1 transition, $O(k^1)$ terms the mixed (E1-E2) and (E1-M1) transitions, and $O(k^2)$ terms the E2 and M1 transitions. It is remarkable that a single susceptibility describes all these polarization effects. Furthermore, this constitutive equation can be reversibly rewritten into the four equations of ($\mathbf{E}$ and $\mathbf{B}$) induced (electric and magnetic) polarizations. For that purpose, we note the relation $\mathbf{I} = \partial\mathbf{P}/\partial t + \nabla \times \mathbf{M}$, which holds as both operators and expectation values. If we write the new constitutive equations as $\mathbf{P} = \chi_{\text{eE}}\mathbf{E} + \chi_{\text{eB}}\mathbf{B}$ and $\mathbf{M} = \chi_{\text{mE}}\mathbf{E} + \chi_{\text{mB}}\mathbf{B}$, the new susceptibilities are given as

$$\chi_{\text{eE}} = \frac{1}{\omega^2 V} \sum_v \left[\bar{g}_v \left(\bar{\mathbf{J}}_{0v} + i\mathbf{k}\cdot\bar{\mathbf{Q}}_{0v}^{(e2)} \right) \left(\bar{\mathbf{J}}_{v0} - i\mathbf{k}\cdot\bar{\mathbf{Q}}_{v0}^{(e2)} \right) + \bar{h}_v \left(\bar{\mathbf{J}}_{v0} + i\mathbf{k}\cdot\bar{\mathbf{Q}}_{v0}^{(e2)} \right) \left(\bar{\mathbf{J}}_{0v} - i\mathbf{k}\cdot\bar{\mathbf{Q}}_{0v}^{(e2)} \right) \right], \quad (44)$$

$$\chi_{\text{eB}} = \frac{-i}{\omega V} \sum_v \left[\bar{g}_v \left(\bar{\mathbf{J}}_{0v} + i\mathbf{k}\cdot\bar{\mathbf{Q}}_{0v}^{(e2)} \right) \bar{\mathbf{M}}_{v0} + \bar{h}_v \left(\bar{\mathbf{J}}_{v0} + i\mathbf{k}\cdot\bar{\mathbf{Q}}_{v0}^{(e2)} \right) \bar{\mathbf{M}}_{0v} \right], \quad (45)$$

$$\chi_{\text{mB}} = \frac{1}{V} \sum_v \left[\bar{g}_v \bar{\mathbf{M}}_{0v} \bar{\mathbf{M}}_{v0} + \bar{h}_v \bar{\mathbf{M}}_{v0} \bar{\mathbf{M}}_{0v} \right], \quad (46)$$

$$\chi_{\text{mE}} = \frac{i}{\omega V} \sum_v \left[\bar{g}_v \bar{\mathbf{M}}_{0v} \left(\bar{\mathbf{J}}_{v0} - i\mathbf{k}\cdot\bar{\mathbf{Q}}_{v0}^{(e2)} \right) + \bar{h}_v \bar{\mathbf{M}}_{v0} \left(\bar{\mathbf{J}}_{0v} - i\mathbf{k}\cdot\bar{\mathbf{Q}}_{0v}^{(e2)} \right) \right]. \quad (47)$$

χ_{eE} and χ_{mM} are usual electric polarizability and magnetic susceptibility, respectively. The rewriting of (38) into the two equations relating ($\mathbf{P}, \mathbf{M}$) with ($\mathbf{E}, \mathbf{B}$) does not break the single susceptibility nature of the theory, because the rewriting is reversible. In this sense, these four equations may still be called single susceptibility scheme.

Phenomenology of chiral polarization

The terms χ_{eB} and χ_{mE} represent cross polarizations, i.e., E -induced P and B -induced M . They are the microscopic expressions of chiral susceptibilities. Materials with chiral symmetry have the excited states of mixed E1 and M1 transitions, which contribute to the finite values of χ_{eB} and χ_{mE} .

The EM response of chiral systems has traditionally been treated via Drude-Born-Fedorov constitutive equations (Band, 2006)

$$\mathbf{D} = \varepsilon(\mathbf{E} + \beta \nabla \times \mathbf{E}), \quad \mathbf{B} = \mu(\mathbf{H} + \beta \nabla \times \mathbf{H}). \quad (48)$$

This is a phenomenology for uniform, isotropic chiral systems (Lakhtakia, 2000). It was derived, not by quantum mechanical calculation, but from symmetry consideration (Drude, 1912; Born, 1933; Fedorov, 1959a, 1959b). A contrasting phenomenology can be made from the result of the previous subsection. We rewrite the r.h.s. of $\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}$, $\mathbf{H} = (1/\mu_0)\mathbf{B} - \mathbf{M}$ in terms of $\mathbf{E}$ and $\mathbf{B}$ as

$$\mathbf{D} = \varepsilon \mathbf{E} + i\zeta \mathbf{B}, \quad \mathbf{H} = (1/\mu)\mathbf{B} + i\eta \mathbf{E}. \quad (49)$$

where the coefficients ε , ζ , μ , η are given as

$$\varepsilon = \varepsilon_0 + \chi_{eE}, \quad \mu = 1/\mu_0 - \chi_{mB}, \quad \zeta = \chi_{eB}, \quad \eta = -\chi_{mE}. \quad (50)$$

Regarding them as macroscopic parameters, we have another phenomenological form of chiral constitutive equations, which we denote here ChC equations. The parameters describing chiral effect in these equations are β and (ζ, η) .

Though the two sets of macroscopic equations might look rather similar, they are quite different. The normal mode dispersion is given as

$$\frac{ck}{\omega} = \pm \frac{\sqrt{\varepsilon\mu}}{1 \pm (\beta\omega/c)\sqrt{\varepsilon\mu}} \quad (51)$$

for DBF equations, and

$$\frac{ck}{\omega} = \pm \frac{2\varepsilon\mu}{\Lambda \pm \sqrt{\Lambda^2 + 4\varepsilon\mu}} \quad (52)$$

for ChC equations, where $\Lambda = \mu(\zeta + \eta)$. The expression in the square root determines the range of real branch, to which β does not contribute in DBF case, but (ζ, η) do in ChC case. This is also connected with the clear distinction about the absence and occurrence of linear crossing in the resonant region of dispersion curves in left-handed medium (Cho, 2018). These results indicate the preference of ChC to DBF equations as phenomenology.

Comparison of different single susceptibility theories

The present scheme of single susceptibility theory uses the three components of current density as the minimal necessary variables. Another choice is possible, and actually an example was shown by Landau and Lifshitz (1963). What they chose for this purpose is “generalized polarization $\mathbf{P}^{(LL)}$ containing $\mathbf{M}$ ” through the definition $\partial \mathbf{P}^{(LL)}/\partial t = \mathbf{J}$. The third possibility in this connection is “generalized magnetization $\mathbf{M}^{(A)}$ containing $\mathbf{P}$ ”, defined by $\nabla \times \mathbf{M}^{(A)} = \mathbf{J}$ (Chipouline et al., 2012). But the lack of L component in $\mathbf{M}^{(A)}$ does not allow the comparison with the other two cases. In order to make proper comparison, we need to restrict their difference only in T components, while keeping a common L component. The appropriate choice is (a) $\{\mathbf{P}_T^{(LL)}, \mathbf{J}_L\}$, (b) $\{\mathbf{M}_T^{(A)}, \mathbf{J}_L\}$, and (c) $\{\mathbf{J}_T, \mathbf{J}_L\}$. Though the case (a) is the first proposal as a single susceptibility theory, the corresponding susceptibility was not worked out thoroughly. It is only in case (c) that the full quantum mechanical form of susceptibility is derived. Knowing this result, we can easily derive the susceptibilities of (a) and (b). From the definition of $\mathbf{P}^{(LL)}$ and $\mathbf{M}^{(A)}$, we can write their T components as

$$\mathbf{P}_T^{(LL)} = (i/\omega)\mathbf{J}_T, \quad \mathbf{M}_T^{(A)} = (i/k^2)\mathbf{k} \times \mathbf{J}_T \quad (53)$$

Substituting the constitutive equation of (c) in the $\mathbf{J}_T$ on the r.h.s., we get $\mathbf{P}_T^{(LL)}$ and $\mathbf{M}_T^{(A)}$ as functions of source EM field, namely their constitutive equations. In this sense, we can formulate different single susceptibility theories with any one of these variables (Cho, 2018). However, the use of unfamiliar physical quantity, $\mathbf{P}_T^{(LL)}$ or $\mathbf{M}_T^{(A)}$, would need a particular motivation, while the use of $\mathbf{J}_T$ is a standard procedure.

Conclusion

The main part of the revision is made in Section “Generalization of polarizability” to strengthen the base of semiclassical EM response theory with respect to (i) the choice of minimal necessary number of the variables for description, combined with (ii) the natural consequence of gauge invariant single susceptibility theory. It is stressed that the quantum mechanical form of chiral susceptibility is given in model-independent manner by this formulation, of which consequence is discussed in the macroscopic form of ChC vs. DBF equations. Altogether, the content of this chapter provides a sound basis of EM response theory for a very general class of problems.

The next stage of this theory will be its application to various problems. In Cho (2003) many examples are discussed about the size and shape dependent optical responses of semiconductor samples. One of the nice aspects of these treatment is the possibility of size dependent analysis beyond LWA, which extends the credibility of arguments. On the other hand, there are many different types of materials with corresponding properties and EM responses. Spectroscopy and transport are standard categories of EM response, and optical manipulation for nanoscale materials is a new branch (Ishihara, 2021). Another new area of this topic may be the emergent EM (EEM) theory, which seems to require certain extension of EM response theory for less simple matter systems having, e.g., permanent electric and/or magnetic polarizations.

The starting equations of EEM and the single susceptibility theories are very similar, i.e., the Schrödinger equation in a EM field with relativistic correction terms (spin-orbit interaction, spin Zeeman term, etc.), called Pauli equation, for charged particles. A new aspect with EEM is that it has two types of gauge symmetry, the standard U(1) symmetry and spin related SU(2) symmetry. The latter arises from the inclusion of spin-orbit interaction. However, in the fundamental papers of the field (Nagaosa and Tokura, 2012; Frölich and Studer, 1993; Leurs et al., 2008), there seems to be a controversial points about the form of this term and whether or not the SU(2) symmetry exists.

In the calculation of relativistic correction terms from Dirac equation, one assumes that the rest energy (mc^2) is much larger than all of the kinetic energy of charged particle, the EM field energy, and the interaction energy of particle and EM field. If we do it properly, we need a revision of the spin-orbit interaction in (22) by the replacements $\mathbf{p} \rightarrow \mathbf{p} - e\mathbf{A}$ and $E_L \rightarrow E$.

Relativistic correction affects, not only the motion of charged particles, but also the source terms of Maxwell equation. An obvious example is spin Zeeman term, which contributes as spin dependent current density $\nabla \times \mathbf{M}_s$. The spin-orbit term mentioned above could also have a similar effect. However, these effects on the source term of Maxwell equations are not considered in both of EEM and single susceptibility theory.

One possible future problem for the single susceptibility theory would be the comparison with EEM theory and the effect of revised $\mathcal{H}_{SO}$ on the source terms of Maxwell equations. In view of the same starting (Pauli) equation for both theories, it is desirable to clarify where and how their difference appears.

Abstract

Correlated materials display macroscopic properties arising from short-range electronic interactions. Dynamics of the lattice, electrons and spins faster than the time required to reach thermodynamical equilibrium can be photo-induced, manipulated and detected. Despite the remarkable progress in understanding the equilibrium physics of correlated materials, this approach has succeeded in disclosing a plethora of novel phenomena. After the illumination, the relaxation toward equilibrium via non-equilibrium states takes place on the femtosecond and picosecond timescales. During this process, correlated materials display macroscopic properties not-observable in the thermodynamic phase diagram. This research field discloses even the potential to implement the photo-induced manipulations of the macroscopic electronic and magnetic properties of correlated materials in applications, such as information technology.

Key points

- Introducing the unique possibilities provided by ultrafast spectroscopic methods, concerning correlated materials.
- Comprehensive description of the ultrafast optical techniques, able to induce and track electronic, lattice and spin dynamics with femtosecond time-resolution.
- Summary of the milestone experimental achievements reported in the literature so far for a few specific material classes, namely magnetic materials, ferroelectrics, magnetoelectrics and multiferroics, magnetoelastic media, high-T_c superconductors and Mott insulators.
- Brief description of the theoretical and computational methods relevant for correlated materials.
- Outlook of the possible developments of the research field of correlated materials.

Introduction

Correlated materials are solids, in which short-range classical and/or quantum mechanical interactions between electrons result in cooperative macroscopic phenomena and order. Examples of such ordered states of matter are ferromagnetism, ferrimagnetism, antiferromagnetism, ferroelectricity, multiferroicity, superconductivity. Despite the quantum mechanical origin, a substantial progress in understanding the physics of correlated materials was achieved using the laws of thermodynamics and classical mechanics, by introducing the concept of order parameter (Landau and Lifshitz, 1984). Thermodynamics appeared to be very helpful in understanding ground states of correlated materials. In particular, different macroscopic phases and phase transitions can be observed, as external parameters (temperature, pressure, magnetic and electric fields, strain) are adiabatically varied. These

observations can be explained in terms of the laws of thermodynamics, as the concept of thermodynamic equilibrium properly applies (Landau and Lifshitz, 1980).

As a consequence of the invention and the development of femtosecond lasers, condensed matter physicists have obtained the fastest ever stimulus—bursts of electromagnetic fields with durations down to a few femtoseconds and, more recently, even hundreds of attoseconds. These stimuli are able to excite media on a timescale much faster than the characteristic times of spin-spin, spin-lattice, electron lattice and even electron-electron interaction in solids (Shah, 1996). Dynamical processes on a timescale shorter than the time required to reach thermodynamic equilibrium (i.e., sub-100 ps) are conventionally called *ultrafast* (Giannetti et al., 2016). Femtosecond laser pulses can directly excite specific electronic or phononic transitions. Electronic, lattice and spin resonances can be driven by ultrashort laser pulses via the process of stimulated Raman scattering (Shen and Bloembergen, 1965; Pershan et al., 1965; Pershan, 1963; Shen, 2003). Moreover, femtosecond laser excitation can generate nearly single cycle THz pulses, ultrashort pulses of charge (Smith et al., 1989) or spin-currents (Battiato et al., 2010; Lichtenstein et al., 2011). In the simplest case, relying on absorption of femtosecond laser pulses, the latter can be used as an ultrafast heater. All the mentioned (sub)-picosecond stimuli bring matter into a strongly non-equilibrium state, for which the conventional description of correlated materials in terms of thermodynamics is no longer valid. More particularly, these stunningly short stimuli can:

- inducing phase transitions and activating functionalities, expressed by the different regions of the phase diagram, at an unprecedented speed;
- create new non-equilibrium states, not present in the thermodynamic phase diagrams, and initiate phenomena in these states, which cannot be accessed via equilibrium spectroscopies;
- select and drive the non-equilibrium excitation and relaxation channels, by addressing specific transitions to induce or to detect;
- induce coherent collective electronic, phononic and magnetic modes, while avoiding an increase of entropy. The interaction between a coherent mode, which typically implies dynamics of the order parameter, and the other degrees of freedom can then be accessed.

A particular group of correlated materials, so-called *strongly correlated materials*, exhibits peculiar electronic properties, such as high-temperature superconductivity, charge- or spin-density-wave and the metal-insulator transition (Giannetti et al., 2016). These compounds are generally described by means of the Hubbard model, or more sophisticated versions of it, as they are elusive of the band-theory. The reason is that electronic correlations and interactions play a major role in shaping both the electronic ground- and the excited-states, while band-theory presents a single-electron description of solids.

Among all types of correlated materials, non-equilibrium states triggered by femtosecond laser pulses are most actively studied in media with long-range magnetic order, i.e., ferro-, ferri- and antiferromagnetic materials. Here we are going to provide: (i) a description of the experimental methods in ultrafast spectroscopy of correlated materials, providing a few examples of remarkable observations allowed by these methods; (ii) a general overview of the experimental and theoretical milestones achieved in ultrafast magnetism; (iii) a brief description of ultrafast phenomena in different classes of correlated materials.

Methods

The cornerstone of ultrafast spectroscopic approaches is the *pump-probe* technique, which is based on the idea of exciting the medium by means of an intense pulsed laser beam (the *pump*) and detecting the dynamical evolution of macroscopic observables in the material, as a result the interaction between the sample and another beam (the *probe*). This simple concept can be realized in a wide variety of schemes, aimed at detecting different macroscopic quantities of a given medium, as discussed in the following. Fig. 1 shows how different implementations of the detection in the pump-probe schemes allows to selectively monitor the ultrafast dynamics of different degrees of freedom in solids.

Fig. 1 Methods enabling the detection of the dynamics of different reservoirs of energy.

As for the pump, we define three distinct experimental regimes:

- *Weak perturbation.* The pump excites non-thermally quasiparticles, without qualitative changes of the general properties of the system, i.e., the medium remains in the original phase and no major changes of the shape of the thermodynamic potential occur. The concept of *effective temperature* is introduced to describe the quasi-equilibrium state of various reservoirs of energy (electrons, lattice, spins) in the medium. This state is portrayed as in equilibrium albeit with increased temperature, in comparison with the state prior to the photoexcitation.
- *Strong perturbation.* The pump beam drives the system so far from equilibrium, that a transition to either a different region of the thermodynamical phase diagram or even to a phase not accessible at all via adiabatic transformations is induced. The strong perturbation regime is vastly explored aiming at manipulating the macroscopic electronic (metal-insulator transition, superconductivity, charge-density wave), lattice (structural phase transitions) and magnetic (reversal of the order parameter, magnetic phase transitions) on the ultrafast timescale made available by the duration of the laser pulses.
- *Coherent macroscopic dynamics of the order parameters.* Coherent oscillations of order parameters (electronic, magnetic, vibrational) can be induced by an impulsive excitation. The lowest order coupling between high-frequency light waves and low-frequency coherent modes is mediated by Raman processes. Therefore the cross-section, selection rules and time-scale of the oscillatory signals (both frequency and lifetime) can be inferred from the Raman spectrum of the material.

State-of-the-art ultrafast spectroscopic experiments enable to investigate the optical properties in a gigantic spectral regime, spanning the THz—X-rays range, in combination with temporal resolutions entering even the attoseconds scale.

Single-color pump-probe spectroscopy

Table-top femtosecond laser sources combined with the lock-in detection (or an equivalent digital version of it) enable to monitor the transient changes of the optical properties, i.e., reflectivity or transmissivity, with a signal-to-noise ratio as high as 10^{-8} (Giannetti et al., 2016). The typical repetition rate of the source is in the kHz regime, although MHz amplified laser systems are already available. Fast digitizers allow even single-pulse measurements. The addition of waveplates and polarizing optics, such as a Wollaston prism, before the detector enables both the measurement of additional quantities (i.e., rotation and ellipticity of the probe polarization) and an increased sensitivity, as the intensity fluctuations of the light source are canceled. This scheme, called balanced detection, is vastly employed for experiments in magnetic materials, as magneto-optical effects allow to track the pump-induced ultrafast spin dynamics via the detection of the rotation and ellipticity of the polarization of the probe beam.

The most common laser sources employed rely on Titanium sapphire (Ti:Sa) as active medium. Consequently the laser pulses have central photon energy of 1.55 eV. In the introduction we discussed already the advantages provided by the tunability of the photon energy, which is achieved by means of non-linear optical interactions. The simplest approach is to generate harmonics of the fundamental frequency of the laser relying on non-linear crystals. A more sophisticated approach, allowing to cover the visible, near infrared and near ultra-violet spectral range (0.5–3.5 eV) consists in employing optical parametric amplifiers (OPA). These devices allow to tune almost continuously the photon energy of a beam in the aforementioned range. Considering the goal of driving and investigating ever faster processes, it is worth to mention that the non-collinear scheme of an OPA (NOPA) grants a superior time resolution, as laser pulses with few optical cycles can be synthesized, which means durations comparable to, or even lower than, 10 fs throughout the tunability spectral range can be achieved. The beams generated by an OPA can be further employed for non-linear optical interactions, so that ultrashort laser pulses in the mid-IR spectral range (photon energy below 0.20 eV) can be generated. This particular energy regime is relevant in order to explore the resonant drive of lattice and magnetic collective modes.

A further extension of the pump-probe scheme consists in multi-pulses technique, in which more than one beam induce a desired state in the material, whose dynamics is then monitored by means of the probe beam. An example is the destruction pump-probe technique, based on the idea that the first (*destruction*) beam quenches a long-range order (i.e., the charge-density-wave) and, in so doing, induces a high symmetry state (Yusupov et al., 2010). From this state a conventional pump-probe experiment is performed, so that the dynamics of the order parameter can be accessed even at any time-instant during the destruction-induced symmetry-breaking process. Another example, which is gaining massive popularity, is the two-dimensional spectroscopy (Nardin, 2015; Cundiff and Mukamel, 2013; Stone et al., 2009; Purz et al., 2021). This scheme allows a direct disentanglement of linear and non-linear contribution to the time-resolved signal, which unravels the possible coupling between several photo-induced modes. We note that the experimental approach typically employed to achieve the coherent control of the amplitude of coherent lattice, charge and magnetic modes, requires two excitation beams as well.

Non-linear optical method are able to track the ultrafast dynamics of the ferroelectric, ferromagnetic and antiferromagnetic order parameter. More specifically, the photon-energy of the probe beam is tuned to be resonant with an electronic transition of the material, so that resonant second harmonic generation can take place. The intensity of this non-linear signal is then detected (Duong et al., 2004). In the case of the ferroelectric polarization, the measurement of SHG is an indirect probe of the dynamic polarization. Conveniently the second harmonic method can be implemented table-top. However, whether the nonlinear optical signal provides reliable informations concerning the dynamics of the ferroelectric polarization is still subject of intense debate. On the other hand, it is paramount to mention, that in the case of magnetic materials, the SHG signal contains multiple different contributions, so that a direct interpretation of SHG dynamics in terms of pure spin dynamics is likely to lead to misinterpretations of the physical processes under investigation (Duong et al., 2004; Huber et al., 2015).

All the approaches discussed so far provides spectroscopic information in rather limited spectral range for each measurements, as the laser beams are *single-color*. A broader spectroscopic response of the material is obtained in consecutive measurements by tuning the photon-energy of the beams with (N)OPAs (Cerullo and Silvestri, 2003; Brida et al., 2009; Manzoni and Cerullo, 2016).

Broadband pump-probe spectroscopy

This approach aims at a time-dependent reconstruction of the frequency-dependent dielectric function. Focusing amplified ($E > 0.5 \mu\text{J}/\text{pulse}$) femtosecond laser pulses in transparent non-linear crystals, it is possible to generate a broadband pulse, so called *supercontinuum*, via self-phase modulation. The width of the supercontinuum ranges from 450 to 1300 nm. Alternatively, the supercontinuum can be generated also with low-energy ($E < 100 \text{ nJ}/\text{pulse}$, i.e., non-amplified) by means of a photonic-crystal fibers.

The intrinsic advantage of this approach, which justifies the increased technical complexity of the experiments, clearly lies in the simultaneous measurement of the spectral dependence of the optical response, in a very broad range. This is a way more robust and solid starting point for the development of effective nonequilibrium models for the dielectric function than single-color measurements (Conte et al., 2012; Giannetti et al., 2016).

Technically this approach can be extended to the time-resolved measurement of the spectral-dependent magneto-optical response of a magnetic material. However, this is far from trivial. Implementing the balanced detection on multichannel detectors requires to disperse the two polarization components of the supercontinuum probe beam in exactly the same way on two different detectors. This is the main reason why this approach has been barely pursued so far.

Time-domain THz spectroscopy

The THz spectral range is typically defined as the frequency interval from 0.1 THz ($0.4 \text{ meV} = 4 \text{ K}$) to 5 THz ($20 \text{ meV} = 220 \text{ K}$). Several nonlinear crystals can be employed to generate radiation in this range, by means of optical rectification, for instance ZnTe, GaSe, LiNbO₃ (Kozina et al., 2019; Hudl et al., 2019; Bonetti et al., 2016) and even organic compounds (Unikandanunni et al., 2022; Polley et al., 2018; Brunner et al., 2008; Puc et al., 2019). The electric field produced in this way enters the MV/cm regime. The THz pulses are detected by means of electro-optical sampling: the radiation is sent onto a detection crystal inducing birefringence, which is transferred into the ellipticity of a near-infrared probe beam. This detection scheme allows to detect experimentally both the amplitude and phase of the electromagnetic field throughout its entire spectrum, without relying on the Kramers-Kronig transformation.

THz-pulses can be employed to monitor the optically-induced changes in the optical properties of materials in the THz region, once combined with a visible or near-infrared pump beam. It is worth to mention, that THz pulses have been already successfully employed in multi-pulses schemes, such as the 2D-spectroscopy.

Other time-domain techniques

The concept of the pump-probe scheme can be extended to the following techniques:

- *Time-resolved photoemission.* The pump beam induces dynamics in the material, while the probe beam triggers the photoemission process. The probe photon energy must exceed the work function, thus typically UV photons are necessary. Kinematic constraints require the extreme ultraviolet spectral range, which can be achieved via high-harmonic generation, in order to access the entire Brillouin zone. This method is extremely powerful, as it allows to reconstruct the non-equilibrium band structure of a given medium (Giannetti et al., 2016; Zonno et al., 2021). However, it is also rather limited in terms of material choice, as mostly thin high-quality metallic layers, which have to be prepared in-situ are employed. Semiconductors and dielectrics can be hardly investigated in this scheme.
- *Time-resolved electron and X-ray diffraction, imaging and spectroscopy.* The THz/mid-IR/near-IR/visible/pump beam is combined with an ultrashort X-ray (or electronic) probe beam. In the case of X-rays, this approach has been recently becoming more popular because of the possibility of performing element specific detection at the edges of various elements (Fe, Co, Ni, Cu, Gd, Tb, etc.) using the femtosecond flashes of light from advanced beamlines at synchrotrons and free electron laser (Schmising et al., 2014; Pfau et al., 2012; Kubacka et al., 2014; Johnson et al., 2011; Grübel et al., 2016; Dornes et al., 2019). As far as electrons are concerned, femtosecond electron pulses are generated via photoemission from a cathode.

Ultrafast magnetism

Ultrafast dynamics in ferromagnets

The goal of understanding the response of ferromagnets to femtosecond laser pulses opened up the whole field of ultrafast magnetism in 1996 (Beaurepaire et al., 1996). It was shown that femtosecond laser excitation of metallic Ni causes an ultrafast collapse of the magnetic order (i.e., demagnetization) of the ferromagnet on a timescale of 2 ps. The authors described their data in terms of thermodynamic three-temperature (3T) model, modeling the medium as three reservoirs of energy representing free electrons, ordered spins and lattice, respectively (Agranat et al., 1984). Assuming that femtosecond laser pulses transfer their energy predominantly to the free electrons, thermodynamics predicts that such a transfer will be followed by heat transfer from electrons to the lattice and from the lattice to spins, on the time-scale of electron lattice relaxation ($\approx 1\text{--}2 \text{ ps}$) and spin-lattice relaxation (10–100 ps), respectively. Increasing the spin temperature results in a quench of the spin order, which can experimentally be observed as demagnetization. Experiments demonstrated that the excitation of electrons with femtosecond laser pulses discloses a previously unexplored channel of heat transfer between the electrons and spins on a timescale of 2 ps. The original observations

were followed by a plethora of experimental, computational and theoretical studies of ultrafast demagnetization in ferromagnetic metals, semiconductors and dielectrics. Interestingly, the 3T-model proposed in the very first paper, is still one of main means to describe ultrafast magnetic phenomena in ferromagnetic media. One of the main consequences of the model is that the efficiency of the ultrafast demagnetization depends only on the amount of heat deposited into free carriers, but not on the way of deposition. For instance, ultrashort pulses in THz, infrared and visible spectral range seem to cause similar demagnetization despite the photon energy changes by three order of magnitude (Bonetti et al., 2016; Mashkovich et al., 2020; Shalaby et al., 2016; Chekhov et al., 2021). Ultrafast demagnetization can also be triggered by picosecond-long pulses of charge current.

The attempt to understand the ultrafast demagnetization in metallic multilayers led to interesting developments in spintronics. In particular, it was realized that the ultrafast demagnetization of Fe in Fe/Au bilayer launches super diffusive spin transport into the Au-layer, which results in magnetizing gold (Battiato et al., 2010). Such a spin transport is concomitant by an efficient THz emission due to the spin Hall effect in Au. Substituting Au (Lichtenstein et al., 2011; Battiato et al., 2010) with Pt, Ta and other heavy metals enhances the THz emission (Seifert et al., 2016; Kampfrath et al., 2013). Although in pure ferromagnets ultrafast laser excitation results only in a partial loss of the spin order, in FePt and Co/Pt multilayers repetitive excitation with a sequence of femtosecond pulses of circularly polarized light can lead to magnetization reversal (Lambert et al., 2014). A more conventional approach to the magnetization reversal was explored in ferromagnets using magnetic field pulses with the duration of ≤ 100 ps (Schumacher, 2005; Back et al., 1998, 1999; Acremann et al., 2000, 2001; Gerrits et al., 2002; Stamm et al., 2005; Tudosa et al., 2004). If the magnitude of the magnetization is conserved, by applying the external magnetic field perpendicular to the magnetization results in the strongest torque applied to the spins. If the field is applied only during half a period of the precession, the magnetization is reversed (Back et al., 1999).

Ultrafast dynamics in ferrimagnets

One of the first experiments on ultrafast demagnetization of ferrimagnets showed that femtosecond laser excitation results in a much more dramatic effect. The excitation of ferrimagnetic GdFeCo alloy with a single 40 fs-circularly polarized laser pulse resulted in magnetization reversal, such that the final state was deterministically defined by the helicity of light (Stanciu et al., 2007). The physical picture of this phenomenon is summarized as it follows: femtosecond laser pulses heat free electrons and thus launches the ultrafast demagnetization of antiferromagnetically coupled Gd and FeCo sublattices, respectively. While the demagnetization of FeCo sublattices occurs on a time of 1 ps, the demagnetization of Gd takes much longer. Due to cooling of the electrons via electron-phonon interaction, the process of demagnetization is exhausted at about 2 ps leaving the spin system in a strongly nonequilibrium state. In fact, in this state the FeCo sublattice is nearly demagnetized, while the Gd sublattice is only slightly affected. A relaxation from this state driven by the exchange spin-spin interaction is accompanied by the magnetization reversal resulting in ultrafast writing of magnetic bits. It was shown that the effect is observed only for intensities above a certain threshold, which allows to bring the sublattices far enough from the equilibrium. Using circularly polarized light and relying on magnetic circular dichroism in the ferrimagnet, right and left-handed circularly polarized beams are absorbed differently, so that the process of the magnetization reversal becomes helicity-dependent. The helicity dependence is observed only in a narrow range of intensities (Khorsand et al., 2012). For intensities above this range the magnetization becomes helicity independent and every pulse triggers magnetization reversal (Ostler et al., 2012). It was demonstrated that the bits can be written with a spatial resolution down to 40 nm. Moreover the writing does not necessarily require femtosecond laser pulses, as the process can be activated with the help of picosecond pulses of charges (Yang et al., 2017) or spin currents (Hees et al., 2020) as well. Magnetization reversal induced by femtosecond laser pulses was demonstrated in a broad class of ferrimagnets in the vicinity of their compensation temperature, at which the magnetizations of the antiferromagnetically coupled sublattices are equal and thus cancel each other out (Mangin et al., 2014; Kimel, 2014). The ultimate frequency of repetitive all-optical magnetization reversal in ferrimagnets was studied in Wang et al. (2021). In GdFeCo, for instance, it is shown that although magnetic writing launched by the first pulse is completed after 100 ps, a reliable rewriting of the bit by the second shot requires a delay between the shots of at least 300 ps. In the half-metallic Heusler ferrimagnet $\text{Mn}_2\text{Ru}_{0.9}\text{Ga}$ the reliable rewriting by the second pulse was reported for delays as short as 10 ps (Banerjee et al., 2021).

Interestingly, ferrimagnets facilitate mechanisms allowing to write magnetic domains with the help of femtosecond laser pulses without relying on heat. In particular, using Co-doped yttrium iron garnet (YIG:Co) it was shown that light can effectively control the magnetic anisotropy in the material by means of an active pumping of a $d-d$ electronic transition in the Co^{2+} ions in the tetrahedral and octahedral crystallographic positions, respectively (Stupakiewicz et al., 2017, 2019). The interplay between cubic magneto-crystalline and uniaxial photo-induced anisotropy results in magnetization dynamics, displaying a heavily damped precessional reversal of the order parameter between different metastable states along the cube diagonals. While the unperturbed Co-doped garnet has four axes of magnetic anisotropy, ultrafast laser pumping creates non-equilibrium population of excited states in Co^{2+} ions and thus hardens/softens different axes depending on the polarization of light. Hence using linearly polarized femtosecond laser pulses it is possible to write and read magnetic domains (bits) in such an iron garnet, without relying on the optical excitation of free electrons. A write-read event was accompanied by an unprecedentedly low heat load (5 aJ when normalized to a $(10 \text{ nm})^3$ bit) and could be repeated at a rate of 20 GHz (Szerenos et al., 2019), where the latter is practically defined by the frequency of spin resonance in this compound.

Ultrafast dynamics in antiferromagnets

As the frequency of the spin resonance in antiferromagnets can be 1000 times higher than in ferromagnets (Kittel and Kittel, 1951), it can be expected that the reorientation of spins occurs up to a 1000 times faster. Moreover, the minima of the thermodynamic potential in antiferromagnets have equivalent energies, entropies and angular momenta, i.e., writing bits by rotating antiferromagnetic spins does not imply an irreversible transfer of energy or angular momentum between the lattice and the spins. Hence almost from the early days of ultrafast magnetism antiferromagnets have been considered as a promising playground in the quest for the fastest and the least dissipative data storage.

The first experimental studies of spin dynamics triggered in antiferromagnets by femtosecond laser pulses were focused on the class of weak ferromagnets (Kimel et al., 2002). Due to the Dzyaloshinskii-Moriya interaction, antiferromagnetically coupled spins are slightly canted from the purely antiparallel orientation. The canting results in a small magnetization, which greatly simplifies experimental studies of antiferromagnetic materials. In particular, it allows the manipulation of spin structures with the help of relatively small magnetic fields. The detection of antiferromagnetically coupled spins is carried on via the magneto-optical Faraday effect, similarly to ferro- and ferrimagnetic materials. A particular attention in this research was given to rare-earth orthoferrites. These systems host several magnetic phases and exhibit spin reorientation phase transitions induced by temperature, strain and/or magnetic field. Launching such a spin-reorientation phase transition in TmFeO_3 via ultrafast heating with the help of femtosecond laser pulses, it was shown that spins in antiferromagnets can be reoriented at the record breaking speed and potentially facilitate writing of magnetic bits at THz rates (Kimel et al., 2004). Recently, it was shown that the very same phase transition can be initiated without heating, but by pumping an electronic $f-f$ transition in Tm^{3+} ions with the help of intense, nearly single-cycle THz pulses (Baierl et al., 2016; Schlauderer et al., 2019).

FeRh is another example of intensively studied antiferromagnet. Heating this antiferromagnet above 350 K triggers a counter-intuitive phase transition to a ferromagnetic state. These magnetic changes are accompanied by lattice expansion. Whether this is a magnetic phase transition, which results in structural changes, or whether the structural phase transition is accompanied by magnetic changes, has been a daunting question for several decades (Kittel, 1960; Tu et al., 1969; McKinnon et al., 1970; Myasov, 2005). It was believed that performing time-resolved measurements of spin and lattice dynamics induced by femtosecond heating, the dilemma could be solved (Ju et al., 2004; Thiele et al., 2004; Bergman et al., 2006; Radu et al., 2010). However, it is still a subject of intense debates.

Also antiferromagnets with fully compensated magnetic sublattices have been receiving increasingly high attention over the last decades. Intuitively it may be assumed that the lack of magnetization in the ground state makes these materials not responsive to a magnetic field less intense than 1 T. Nevertheless, the situation is profoundly different, if the field rapidly varies in time. Already 40 years ago it was theoretically predicted that dynamics of spin in antiferromagnets can also be launched by a relatively small external magnetic field, if the latter is not constant (Zvezdin, 1979; Ivanov et al., 1985; Zvezdin and Mukhin, 1981; Andreev and Marchenko, 1980). Kampfrath et al. (2010) showed that a linear coupling of the THz magnetic field to the sublattice-magnetizations triggers coherent spin oscillations, at the frequency of antiferromagnetic resonance in NiO . Similar coherent spin oscillations could also be excited via a nonlinear coupling mechanism of light to spins (Satoh et al., 2010). In both cases, the role of a driving force is played by the time derivative of the effective magnetic field $\partial H/\partial t$. The observation of the coherent spin oscillations in the antiferromagnet was achieved by measuring the magneto-optical Faraday effect. Although for unperturbed compensated antiferromagnets both the magnetization and the magneto-optical Faraday effect vanish, a signal emerges due to the excitation of coherent spin oscillations at the frequency of the antiferromagnetic resonance.

In antiferromagnets, it is possible to generate coherent spin waves near the very edges of the Brillouin zone, by means of sub-10 fs laser pulses (Bossini et al., 2016, 2019; Bossini and Rasing, 2017). The interplay between spins and lattice in antiferromagnets seems to play the central role in the formation of antiferromagnetic domains. Understanding the role of the lattice in spin dynamics in antiferromagnets can appear to be crucial for the development of antiferromagnetic data storage. In the very recent years, several counter-intuitive experimental observations further fueled interest into magnetoelasticity (Bossini et al., 2021b), piezomagnetism and phonomagnetism.

Although several computational and theoretical studies have already claimed the possibility of record fast writing of antiferromagnetic bits using ultrashort stimuli such as THz magnetic field pulses, femtosecond spin (photo)currents and even femtosecond laser pulses, none of the experimental time-resolved studies of spin dynamics in antiferromagnets has demonstrated the writing of bits at a picosecond timescale (Wienholdt et al., 2012; Chirac et al., 2020; Dannegger et al., 2021). Moreover, the majority of the experimental reports of spin dynamics in antiferromagnets showed merely a harmonic response, which suggests only a small perturbation of the spins in the vicinity of the equilibrium state. At the same time, Olejník et al. (2018) showed that excitation of antiferromagnetic CuMnAs in a multidomain state with GHz or THz pulses can switch the magnet between multiple stable states. Reversible optical switching of antiferromagnetic domains in TbMnO_3 was reported in Manz et al. (2016). However, none of these papers reported about the actual dynamics of the switching. Very recently, employing ultrafast pumping of Tm^{3+} ions in antiferromagnetic TmFeO_3 with the help of intense THz pulses, it was possible to drive spin dynamics in this antiferromagnet into an anharmonic regime. In particular, the triggered dynamics even acquired characteristic features showing that in a part of the sample the spins were navigated over a potential barrier (Schlauderer et al., 2019). However, ultrafast writing of antiferromagnetic bits has not yet been demonstrated, calling for either stronger stimuli for antiferromagnetic spins or more efficient mechanisms for antiferromagnetic switching.

Aiming at applications in terms of data storage, the ability to convert ultrafast spin dynamics into a charge-signal must be developed. This milestone would allow an integration of this novel technological paradigm with nowadays available CMOS technology. Correlated antiferromagnets provide also a promising platform in this sense. It has been known since long that spins and charges are intrinsically coupled in the ground state of several antiferromagnetic semiconductors (Ferrer-Roca et al., 2000). More precisely the energy of the bandgap has a magnetic contribution, quadratic to the antiferromagnetic order parameter (Bossini et al., 2020; Güntherodt et al., 1971). While early attempts to exploit this property in dynamics have already been reported (Deltenre et al., 2021; Subkhangulov et al., 2014; Bossini et al., 2021a; Formisano et al., 2020), it has been realized that this coupling is not specific of a few peculiar materials. Actually it has been demonstrated that any correlated antiferromagnet, i.e., an antiferromagnet that can be described in the framework of the Mott-Hubbard theory, displays the coupling between band-gap and magnetic order (Hafez-Torbati et al., 2021).

Ultrafast dynamics in ferroelectrics

The traditional method to manipulate the ferroelectric polarization relies on static or pulsed electric fields. The mechanism responsible for the reversal of the polarization in this case is the nucleation and growth of oppositely polarized domains. Consequently the speed of switching with this approach is inherently limited to hundreds of picoseconds (Mankowsky et al., 2017).

A possible route to ultrafast coherent dynamics and even reversal of the polarization in ferroelectric consists in driving the soft-mode (Fahy and Merlin, 1994). This particular phonon possesses the same symmetry of the order parameter and, as the name suggests, it softens at the critical temperature. THz pulses have been employed in multiple ferroelectrics to resonantly excite the phonon mode. The corresponding ionic motion has been tracked by means of X-rays scattering (Grübel et al., 2016). A quantitative estimation of the modulation of the polarization gave a 8% value. Simulations predict the same approach to be able to induce even a reversal of the ferroelectric polarization, provided that the electric field of the THz pulses reaches the MV/cm regime, which is possible with nowadays sources (Kimel et al., 2020; Grübel et al., 2016).

Alternatively it has been predicted that the impulsive stimulated Raman scattering excitation of the ferroelectric mode should enable the ultrafast reversal of the polarization (Fahy and Merlin, 1994). This method successfully resulted in generating coherent and strongly anharmonic dynamics of the ferroelectric mode, but no switching (Brennan and Nelson, 1997).

Recently the nonlinear phononics approach has been explored in LiNbO₃ (Mankowsky et al., 2017). The excitation of the ferroelectric soft mode could be achieved indirectly, by exciting a vibrational mode in mid-infrared spectral range, which is anharmonically coupled to the soft mode. The authors tracked the dynamics of the order parameter by means of time-resolved second harmonic generation (SHG). The experimental results were interpreted in terms of a femtosecond switching of the ferroelectric polarization, although the claimed switched state was not stable (Mankowsky et al., 2017). This work is indeed interesting and controversial, as the theoretical model of the switching of the polarization employed by the authors has been questioned (Mertelj and Kabanov, 2019).

Ultrafast dynamics in magnetoelectrics and multiferroics

The coexistence of the ferroelectric polarization and of the magnetic ordering in the same structure has potential for the realization of storage devices, provided that the two orders can be optically coupled on the ultrafast timescale.

Two main material classes have been explored: composite (or artificial) multiferroics and natural magnetoelectric multiferroics.

The former are 1-, 2-, or 3D heterostructures, which combine the coupled magnetically ordered and ferroelectric constituents. It is thus appealing to use such structures, in which the order parameter in one of the layers is sensitive to photoexcitation, while another order parameter is controlled via associated strain changes. For instance, ferroelectrics allow the generation of large-amplitude strains due to the femtosecond photoexcitation, because of piezoelectricity. An example of an experimental demonstration of this concept was realized on a Ba_{0.1}Sr_{0.9}TiO₃ (BSTO)/La_{0.7}Ca_{0.3}MnO₃ (LCMO) heterostructure: the laser-induced demagnetization results in strain via magnetostriction. Such strain induces dynamics of the electric polarization, tracked via transient SHG (Sheu et al., 2014).

Natural multiferroics have been hitherto not extensively investigated, especially as far as the optical modification of the magnetoelectric coupling is concerned. Often these materials have been regarded as conventional magnetic materials. However, the presence of the magnetoelectric coupling allows unique and peculiar excitations. For instance, relying on the impulsive stimulated Raman scattering mechanism, collective coherent lattice and spin modes have been triggered in the multiferroic GdFeO₃ (Sheu et al., 2018). Different detection schemes have been employed to monitor the lattice and spin dynamics. More specifically, time-resolved SHG provided access to the lattice dynamics. On the other hand, the optical transmissivity enabled the measurement of the magnon dynamics. This result is peculiar and remarkable: in a conventional magnetic material, spin dynamics can be detected via magneto-optical effects only, as the optical properties are not coupled to spins. Differently, in a multiferroic the magnetoelectric coupling provides an additional contribution to the optical response, which is proportional to the magnetization. This concept has been demonstrated in a very neat way in GdFeO₃ (Sheu et al., 2018).

Another peculiar phenomenon in multiferroics is the electromagnon: this is an electric-dipole active spin excitations directly connected to the magnetoelectric coupling. In a time-resolved experiment, THz laser pulses have been shown to resonantly drive this transition in TbMnO₃ (Kubacka et al., 2014). The consequence of the photo-excitation for the magnetic systems have been

detected via resonant X-ray diffraction. This excitation mechanism, relying on the electric field of light, generates a modulation of the magnetic signal one order of magnitude bigger than the canonical magnetic-field induced spin precession (Kubacka et al., 2014).

Finally we would like to mention two works reporting photo-induced phase transitions in magnetoelectric materials. The relevance of these experiments lies in the phase diagram of the materials investigated, as the transition from a non-magnetoelectric to a magnetoelectric phase is optically induced. Nearinfrared laser pulses induce a picosecond magnetic phase transition in CuO, which was tracked by means of resonant X-ray diffraction. A phase transition from the collinear (non-magnetoelectric) to the spiral (magnetoelectric) antiferromagnetic phase is reported on the picosecond timescale. The transition shows a rich and complex dynamics, which was resolved in details as it takes place on the picosecond time-scale (Johnson et al., 2011). Another example is CuB₂O₄, whose phase diagram exhibits also two magnetic phases, one of which magnetoelectric. In this material, high-energy magnons can be resonantly induced by means of near-infrared laser pulses, because of an hybridized electronic and magnonic transition, the so-called exciton-magnon. The resonant drive of high-frequency and short-life-time spin excitations perturbs the magnetic ground state so strongly, that the phase transition was observed in less than 1 ps (Bossini et al., 2018). The magnetoelectric phase can be unambiguously detected with pure optical methods, as the magnetoelectric coupling enables new optical phenomena proportional to the magnetic ordering (Toyoda et al., 2016, 2015). From the theoretical side, it was predicted- that a time-dependent electric polarization can induce a magnetization, even in materials lacking a longrange magnetic order. This effect has been called dynamical multiferroicity (Juraschek et al., 2017).

Ultrafast phono-magnetism

In this section we would like to highlight a more general concept of coupling lattice dynamics to the motion of a macroscopic order parameter. The coupling of the lattice, in either the form of phonons or strain waves, to spins in magnetic (ferro-, ferri-magnets and antiferromagnets) media induces femtosecond coherent and incoherent spin dynamics, even beyond the linear regime. A first example concerns antiferromagnets in multi-domain states: magneto-elastic interactions mediated by the walls can couple different magnon modes in different domains, on the ultrafast timescale (Bossini et al., 2021b; Gomonay and Bossini, 2021).

The material class of rare-earth doped yttrium iron garnet displays also a remarkable magnetoelastic coupling, which can be exploited to trigger ultrafast spin dynamics. For instance, time-resolved magneto-optical imaging was employed to detect photo-induced magnetoelastic waves in Lu-doped yttrium iron garnet. The processing of the data allowed to reconstruct the dynamics of the dispersion of both the spin and elastic waves (Hashimoto et al., 2017, 2018). Moreover, the optically induced strain allowed to manipulate the frequency of the magnetic resonance in a 17 nm-thick crystal of Bismuth-doped yttrium iron garnet. This approach resulted in a 20% increase of the resonance frequency, attained via a manipulation of the magnetoelastic coupling due to the optically-triggered strain waves (Soumah et al., 2021).

Strain waves can also be generated optically heating a metallic layers deposited on the back of the sample of interest. This layer works as a transducer. The illumination induces a femtosecond expansion, which results in the generation of a strain wave. This approach has been demonstrated to be able to trigger coherent precession of the magnetization in ferromagnetic semiconductors (Scherbakov et al., 2010) and metals (Jäger et al., 2015).

The resonant pumping of phonons, with the proper frequency and symmetry, can result in the generation of coherent magnons (Nova et al., 2016). This effect consists in essence in Raman scattering of the phonon fields on magnons, with the very same phenomenology of the canonical inelastic light scattering on magnons (Juraschek et al., 2020). Recently, it was demonstrated that resonant pumping of longitudinal optical phonons results in the switching of the magnetization in iron garnets (Stupakiewicz et al., 2021) and control of the domain texture in antiferromagnets (Stremoukhov et al., 2022).

Ultrafast charge dynamics in superconductors and Mott insulators

The electronic non-equilibrium properties of charge-transfer insulators, Mott-insulators and, specifically, high-T_c superconductors have been massively investigated. Considering that extensive reviews on this topic have been already published, we limit ourselves to a short list of the main experimental findings:

- *Insulator-to-metal transition.* A plethora of reports revealed that the photo-excitation of some transition metal oxides (manganites (Rini et al., 2007), vanadates iron oxides (Pashkin et al., 2011)) can lead to metallicity on the (sub)-picosecond timescale (Giannetti et al., 2016). The prototypical system for this transition is VO₂: below the critical temperature $T_c = 340$ K, this material is in an insulating phase. At ambient temperature, the photo-excitation with visible and near-IR pulses results in a sudden (shorter than 1 < ps) change of the electronic properties: the conductivity increases massively, implying that the highly photo-excited VO₂ reaches a metallic state immediately after photoexcitation (Giannetti et al., 2016).
- *Optical modification of the superconductivity.* Two main milestones have been achieved in cuprates superconductors (Giannetti et al., 2016). A time and spectrally-resolved investigation in the visible and near infrared spectral ranges revealed the relaxation processes, following the optical excitation of a high-T_c superconductors. The combination of this challenging experiment with a differential extended Drude-Lorentz model of the transient reflectivity, allowed to identify spin excitations as the main bosonic interaction channel with electrons. As thus, this experiment strongly suggests the nature of the bosonic-glue of the Cooper pairs

to be magnetic in origin (Conte et al., 2012). Another milestone in the physics of high- T_c superconductivity is the demonstrated light-induced superconductivity in a material with *striped* charge order. The emergence of this peculiar macroscopic charge arrangement suppresses the superconductivity. Mid-infrared laser pulses destroy the striped-order, allowing a transient superconducting state to appear and to be detected by optical means (Fausti et al., 2011).

- *Coherent dynamics of the superconducting amplitude modes.* The amplitude mode of the superconductor corresponds to the oscillation of the order parameter $\eta(t)$ at the double frequency of the superconducting gap $2\Delta_{sc}/\hbar$ (Giannetti et al., 2016). We recall that the order parameter of a superconductor is the expectation value of the number of Cooper pairs, typically expressed in terms of the destruction ($c^\dagger$) and construction ($c^\dagger$) operators of Cooper pairs, i.e., $\eta = \langle c^\dagger c^\dagger \rangle$. The intrinsic oscillation frequency is derived from the microscopic BCS theory and it implies that the collective mode has gained mass. This is similar to the Higgs mechanism in the standard model, that is why the amplitude mode is often referred to as Higgs mode in superconductors. This mode was photo-induced and detected in terms of oscillations of the band-gap by means of time-resolved photoemission spectroscopy and optical spectroscopy (Matsunaga et al., 2014).

Theoretical and computational approaches in ultrafast dynamics of correlated materials

As any other emerging area of physics driven by experiments, ultrafast spectroscopy of correlated materials challenges current theories. At the same time, the need for intuitive models stimulates the search for approximations and/or postulates that would still allow to describe the dynamics in terms of intuitive classical mechanics and equilibrium thermodynamics. In this respect, the 2- and 3-temperature models are among the main theoretical tools allowing to interpret ultrafast dynamics in superconducting and magnetic materials, respectively. For instance, most of theoretical studies of the ultrafast demagnetization of metals either aim at a physical interpretation of the electron-spin interaction postulated in the 3-temperature model or employ the 3-temperature model in atomistic or macromagnetic simulations of ultrafast laser-induced spin dynamics.

Time-dependent density functional theory (TDDFT), which extends density functional theory into the time domain, is a formally exact method for describing ultrafast spins- and charge-dynamics under the influence of an external field. The technique does not require any empirical parameters, it is fully *ab initio*, and it is not only linear but also includes all nonlinear processes naturally as part of the simulation.

Dynamical Mean-Field Theory (DMFT) is seen as one of the most appealing approaches to describe ultrafast dynamics in strongly correlated materials (Mott insulators, superconductors). DMFT is a non-perturbative, yet computationally affordable method that can be used either to solve simple models (Hubbard and related models) or it can be combined with density-functional theory to describe accurately actual solids. It can treat different interactions (electron-electron, electron-phonon) and aspects of the electronic structure of a material without assuming any hierarchy of energy scales.

Conclusion

During the whole history of ultrafast phenomena in correlated materials, the progress in the field was mainly driven by experimental observations and boosted by the development of new experimental techniques. Further development of techniques in THz, XUV and X-ray spectral ranges will allow to improve the sensitivity of the measurements. In this way, THz, visible, XUV and X-ray magneto-optics will provide four complementary views on the same ultrafast phenomenon. It is expected that obtaining the complete experimental information will stimulate further close collaboration between theory and experiments, aimed at the formulation of new approximations and conceptually novel theoretical approaches to describe ultrafast magnetism. The interpretation of ultrafast transient states can also benefit from the on-going rapid developments of theoretical and computational methods for multiscale modeling of non-equilibrium dynamics of essentially quantum systems. It is also expected that in the coming years, the continuously increasing demand for ever faster information processing will significantly fuel the fundamental interest into ultrafast dynamics of charge, orbital and spin degrees of freedom. These developments will naturally stimulate proposals of novel devices that are capable to process and store information at THz rates.

Abstract

Excitons are elementary electrical excitations of crystals. They are bound states of negatively charged electrons and positively charged holes, which makes them neutral composite bosons. They can exist in either tight- (Frenkel) or weak- (Wannier) binding conditions. The most important property of excitons is to be created by photon absorption and to emit photons when they annihilate. This makes optical methods most appropriate for their studies. They constitute driven-dissipative quantum systems characterized by a rich variety of optical, spin, transport and transfer phenomena. They are important for both fundamental and applied aspects of condensed-matter physics.

Key points

- The concept of exciton is central to condensed-matter physics.
- Excitons are among the oldest quasi-particles identified and studied, both theoretically and experimentally.
- Excitons are involved in a broad and varied range of effects, mainly optical ones but not exclusively.
- Excitons are expected to undergo a rich set of quantum phases, from Bose-Einstein condensation to superfluidity passing by quantum crystals, Mott insulators and other nontrivial topological phases.
- Excitons remain complex objects even at the two-particle level, whose properties, role, description and sometimes even existence remain hotly debated.
- There is an increasingly thriving activity on excitons thanks to technological progresses and the emergence of new materials.
- There are rich prospects for unique future applications based on excitons, such as stretchable screens.

Introduction

Historical background: Frankel & Wannier-Mott excitons

The concept—and name—of exciton comes from the soviet theorist [Frenkel \(1931\)](#), starting with his theory for the excitation of atomic states when they are part of a lattice. Excitations in the form of motion or vibrations (sound or heat waves) were already established, by Debye, Tamm, Born and others. Frenkel—who incidentally also named their quantum version as “phonons”—considered instead the case of neutral electronic excitation, that is to say, in raising in energy the quantum state of a single atom in an otherwise frozen (non-vibrating) crystal. The localization of such an excitation does not correspond to a stationary state of the crystal and it is instead diluted over all the atoms in the form of what Frenkel first termed an “excitation wave.” The excited state is then shared by other atoms of the crystal, propagating in this way energy yet with no transfer of charge, as well as momentum yet with no transfer of mass. These running exciton states are the proper stationary states of the static crystal. Such a Frenkel exciton thus describes the situation of an excitation that is not associated with a particular atom, but is travelling from one to another, yet remaining in itself of a size or extent commensurable with the atom. This corresponds to a tight-binding case. Frenkel arrived to the conclusion that the absorption spectrum of a crystal, when not affecting its vibrational state, yields single lines that correspond one-to-one to the absorption lines of an isolated atom of the crystal. This surprising result (at the time) explained why the absorption spectra of solid bodies, which at ordinary temperatures are continuous, break down at low temperatures into spectral lines, as is the case for gases. Such paradoxical observations had indeed been made with the rare earth and iodine spectra, while at higher temperatures, vibrational motion blur this excitonic structure into a continuum. The quantization of such waves and their group packets have been interpreted by Frenkel as giving rise to a particle whose motion is characterized by a wavefunction similar to that of an electron, with a momentum $\mathbf{p}$ and kinetic energy $p^2/(2m^*)$ where m^* is an effective mass. Frenkel named this particle an exciton. A record is found for instance in his 1959 textbook “Introduction to the Theory of Metals” where he writes “*This originating state somewhere does not stay in the place where it was formed but moves uniformly along this or that row of atoms as some particle which I call “an exciton” (“an excitation quantum”).*” Frenkel thus developed a theory of light scattering in crystals that was an analog to Schrödinger’s theory of the Compton effect (scattering of light by a free electron), the electron wave being replaced in his case by his excitation wave. In dielectrics, this also explains why there is no photoconductivity despite the fact that two charges are created in the band model. Pekar reported an interjection during a seminar where this puzzle was being entertained, where Frenkel, after asking why the same phenomenon was not a mystery in gases, simply advised to “*consider a dielectric as a compressed gas.*” This is the foundation of exciton physics. In [Frenkel \(1931\)](#)’s own visionary words: “*the development of the theory sketched above in the quantitative direction [...] does not present any difficulty, for this calculation can be easily reduced to the corresponding calculation for an isolated atom or molecule.*” This fact that characteristics and fingerprints of isolated atoms can survive when the atoms themselves dissolve into an object of an altogether different nature—a solid with a band structure—is an embodiment of the basic idea of *quasi-particles*, the tenet of condensed-matter physics. This similarly allows an electron in the conduction band as well as its absence in the valence band (the “electron-hole,” or “hole” for short) to be treated as negative and positive particles, respectively. This is discussed in more details by [La Rocca \(2022\)](#) in this volume. Beyond the formulation of the exciton as a quasi-particle, Frenkel also analyzed excitons’ interactions with the environment, localization and their optical characteristics. [Frenkel \(1936\)](#) later generalized critically his previous results in order to account for arguments from [Peierls \(1932\)](#) regarding weak excitations, producing what he called “small” excitons, which are now known as *Frenkel excitons*. Since they exist predominantly in molecular (organic) crystals, they are also called “molecular excitons.” Several molecules enter the elementary cell of such crystals, and any of them may be optically excited. The other regime, also anticipated by Frenkel who called them “megaexcitons,” occurs in semiconductors, for instance, in copper peroxide, a popular material of practically all the semiconductor experiments of the 1930s, as well as in the other major classes of semiconductors: germanium, gallium arsenide and the like. [Wannier \(1937\)](#) made a general theory for excitons in the Bloch band continuum, and recognized the case where “*the electron does not escape its hole,*” thus producing no current, despite the fact that the bound electron and hole could be considerably separated in space. They, however, remain correlated, maintaining in particular a well-defined wavevector for their joint propagation. Such large-radii excitons are now known as *Wannier excitons*, and constitute the bulk of excitonic physics in optoelectronics, cf. [Fig. 1A](#). While it is Wannier who derived the Schrödinger equation for the Hydrogen atom for such excitons, it is [Mott \(1938\)](#) who painted the explicit picture for them of an electron and hole bound to each others by the Coulomb interaction in a medium with dielectric constant ϵ and migrating around their center-of-mass. This remains, by far, the predominant description of excitons. For this reason, such excitons are also known as *Wannier-Mott excitons*. While his name did not remain attached to excitons, Peierls was also one of the fathers of their conception.

The existence of excitons

Frenkel’s seminal idea was first received reservedly by the authorities of the time, in particular by Pauli who deemed it to be outright “falsch” (hence not trivial, was Frenkel’s rebuttal). There remained controversy for a while until it became apparent, with [Slater and Shockley \(1936\)](#)’s analysis, that the result was robust to alternative theoretical treatments. The existence of isolated spectral lines, in particular, was drawing attention, since the band-theory of solids precisely dissolves the isolated quantized levels of atoms into continuous bands, so their resurgence was suspicious. Interestingly, modern onlookers of such lines have also raised doubts as to their systematic connection to actual excitons in the system. [Kira et al. \(1998\)](#), for instance, regard this question as a many-body problem of Coulomb-interacting fermionic electrons and holes, which, instead of making transitions between sets of excitons, involve polarization fields. The quantum-mechanical luminescence equations of the electron-hole system happen to produce excitonic resonances, either in absorption or luminescence, even when there is no exciton population in the model. This understanding insists on the difference between the excitonic *polarization* and the excitonic *population*. The former is a complex-valued correlator that probes the transitions permitted by the system, is a coherent quantity subject to dephasing and is

Fig. 1 Basic concepts of excitons: (A) **Frenkel and Wannier excitons**, attached to one site of the crystal or involving widely separated sites, which translates in the energy diagrams as occupying Highest Occupied (HOMO) and Lowest Unoccupied (LUMO) Molecular Orbitals in one case and living in the band structure in the other. As a result, these two types of excitons are of small and large spatial extension, respectively. Both are, however, delocalized throughout the entire crystal (represented as ghostly images), (B) **Direct and indirect excitons** from negligible or large exchanged momentum in the interband transitions, allowing or preventing an optical process (emission or absorption). Here the character of the transition changes from direct in a MoS₂ monolayer (left) to indirect in its bulk, (C) **Spatially direct and indirect excitons** in coupled QWs. The horizontal axis is the growth direction and the energy levels can be biased by an electric field, with electron (up, blue) and hole (red, bottom) wavefunctions localized in one or the other QW, resulting in single-well excitons or, in contrast, little-overlapping wavefunctions excitons with strong dipole moment and long lifetimes, (D) **Intra and Interlayer excitons** in bilayers of 2D-material TMDs (e.g., MoS₂ and WSe₂) implement similar ideas than traditional heterostructures in new generations of materials, (E) **Moiré excitons** occur in 2D-heterostructures for various twisting angles θ between the two sheets, resulting in potentials of varying lengths and geometries. This new degree of freedom is one of the peculiarities of the new 2D materials, (F) **Bright and Dark excitons** are those which, for various reasons, can and cannot couple to light, respectively. A typical factor is conservation of angular momentum, ruled by the spin of the particles, with only spin ± 1 excitons recombining (or being created) with a transfer of angular momentum to (from) the photon. This is ruled by the spin of the light-hole (LH) and heavy-hole (HH) bands, (G) **Valley excitons** arise in so-called valleys in the bandgap, which are minima that occur elsewhere than at the zero-momentum (T) point, typically at the $\pm K$ points on the border of the Brillouin zone. In addition to their spin (red, spin-up; blue, spin-down), electron-hole pairing from different valleys results in momentum-forbidden transitions, leading to more bright/dark configurations (dark shaded in gray). Filling up the bands with more electrons and holes leads to charged valley excitons. (H) **Biexcitons** are the bound states of two electrons and two holes, or two excitons. A biexciton in a QD is sketched with its cascade toward the ground state leading to polarization-entangled photons, which can be hindered by the fine-structure splitting between excitonic states, (I) **Multiexcitons** represent the complicated problem of the identity and description of multiple excitons. Even at the two-exciton level, the indistinguishability of electrons and holes make the formulation in terms of excitons ill-defined. In the presence of even more excitons, charged multi-excitons, trions, quatrions, etc., provide convenient mental pictures which may, however, require independent treatment, (J) **Exciton-polaritons** occur from the strong-coupling between excitons and, e.g., photons, leading to the disappearance of these states as they Rabi oscillate from one type to the other, to give rise to quantum superpositions of a mixed new quasiparticle, in-phase (UP) and out-of-phase (LP) and with new energies which result in a characteristic anticrossing.

not ruled by thermodynamics, while the latter is a real-valued quantity referring to real states (or quasi-particles), subject to relaxation dynamics, equilibrium (if given enough time) and phase transitions. Chatterjee et al. (2004) also find that a plasma of unbound electrons and holes emits at the exciton resonances. Such distinctions are important when it comes to seeking new phases of matter, such as Bose condensation, of particles that may in fact not even be present in the system. The persistence of excitonic lines in a variety of scenarios make the determination of the actual origin a tricky one, with the possibility that the parameter range in which true exciton populations exist is in fact limited despite their ubiquitous manifestation. This conclusion has been amply debated (with as yet no consensual resolution), for instance by Deveaud et al. (2005), although dedicated experimental investigations, such as those by Hägele et al. (1999), tend to confirm that the excitonic problem is indeed more complicated than a bound electron-hole pair popping up and recombining. It could, instead, be explained by much-less intuitive Coulomb-correlation contributions to the photon-assisted recombination of free electron-hole pairs. Kaindl et al. (2003) have sought alternative signatures than spectral lines to evidence the presence of real excitons, including “quasi-particle spectroscopy,” which consists in probing transitions between their Coulombic internal exciton levels, prominently between their 1s and 2p states, which typically falls in the THz range for direct-gap semiconductors. They concluded to a coexistence of excitons with electron-hole pairs but with an ultrafast (quasi-instantaneous) excitonic formation at lower temperatures. Hägele et al. (1999) proposed to measure the electron-hole exchange energy which, when the exciton is bound in the state ψ , is proportional to its electron and hole overlap $|\psi(0)|^2$. This can be obtained from the quantum beating of spin since the exchange energy, when it is present, turns the linear dependence of its frequency on an applied magnetic field into a parabolic one (due to a correction to the Zeeman splitting). They concluded that a dominant population of excitons is present only under stringent experimental conditions. Progress from material science, providing more robust excitons, is helping to bring back an unanimous recognition of excitons. In TMDC materials for instance, excitons are believed by Steinhoff et al. (2017) to prevail over electron-hole plasma even up to room temperature, through balancing processes of a fission-fusion type between the two types.

Another hotly debated problem with excitons is whether they qualify, or even exist, as bosons. The commutator of the annihilation and creation operators of excitons is not 1 but deviates from this bosonic limit by an order na_B^D in D dimensions, giving hope of behaving as good bosons at low enough densities. The composite nature of excitons, however, combined to their large size and delocalized character has been hailed as voiding their validity as interacting bosons already at the two-particle level. Since electrons and holes cannot be attributed to any single exciton, one should deal directly with a fermionic four-particle complex dominated by the Pauli exclusion principle. Illustratively, the interaction of any electron with any hole is part of the exciton-exciton scattering when these particles are assumed to belong to different excitons, but are also constitutive of the excitons themselves when belonging to the same exciton, in which case they should be ignored since they have already been taken into account to bind the exciton in the first place (Fig. 11). Combescot and Betbeder-Matibet (2002), in particular, argue that purely fermionic contributions are of the same order as Coulomb contributions and, more importantly, forbid an effective Hamiltonian, since two-exciton interactions involve all other excitons. This is because Pauli exclusion is intrinsically a N -body effect, which precludes an exact description with a standard two-body interactions, even with some inclusions of the exchange terms. They observed, for instance, that such an ad hoc procedure produces a non-Hermitian Hamiltonian. They conclude that the conventional “bosonization”—which consists in mapping the original fermion problem into one of elementary bosons so as to apply known and familiar techniques—are erroneous and should not be used, but replaced by a many-body theory of “cobosons” (for composite bosons), such as that exposed by Combescot et al. (2008). The extent to which the composite nature of excitons affects the dynamics of several excitons remains a problem of active research.

Overview of excitonic physics

Theory of excitons

Excitons are primarily a theoretical concept: a useful physical picture to capture the essence of a phenomenon which, in its full complexity, fails to adhere exactly to any but a complete, so-called “ab-initio” or “first-principle,” brute force calculation of the Schrödinger equation for the full system with no phenomenological parameters. Although ab initio methods are better suited for ground states calculations (with density functional theory), they can also compute elementary excitations in a self-consistent way and derive optical response. A so-called GW (G is for “Green function” and W refers to screening of the Coulomb interaction) approximation combined to the Bethe-Salpeter equation (describing bound states in quantum field theory, so particularly suitable for excitons), or GW-BSE approach, has proved particularly accurate to reproduce experiments in great details. In such cases, one needs not speak of excitons but focus on the calculated observables and compare them to experiments. The agreement in some cases can be extremely good. Even such approaches remain however limited by computational resources and need to make some approximations, that have to be both understood and controlled. Various models thus derive various excitons in different limits. Frenkel and Wannier excitons are obtained in this way from the same underlying theory but using different basis functions. They both start with the Born-Oppenheimer approximation, that decouples the electrons and ions dynamics so that Schrödinger’s equation can now focus on the electronic wavefunction $\phi(\mathbf{r}_1, \mathbf{r}_2, \dots)$ alone, i.e., for the joint probability amplitude to find the $N \gg 1$ electrons in the crystal at positions $\mathbf{r}_i$. If the crystal is assumed static (frozen atoms), the Hamiltonian retains electrons’ kinetic energies $-\frac{\hbar^2}{2m} \sum_i \nabla_i^2$ (m the electron mass and ∇_i acting on the i th variable of ϕ), the electron-crystal Coulomb interaction $-\frac{1}{4\pi\epsilon} \sum_i \sum_n Z e^2 / |\mathbf{X}_n - \mathbf{r}_i|$ and electron-electron interactions $\frac{1}{2} \frac{1}{4\pi\epsilon} \sum_i \sum_{j \neq i} e^2 / |\mathbf{r}_i - \mathbf{r}_j|$, with Z the number of charges of each atomic site, e the electron charge, $\mathbf{X}_n$ the positions of the atoms, that define the crystal and ϵ the dielectric constant. Since each electron interacts with every atom of the crystal and with every other electron, the problem, although simply formulated, is extremely complicated. The next popular step is the one-electron approximation that breaks ϕ into a product $\phi(\mathbf{r}_1, \mathbf{r}_2, \dots) = A\varphi_1(\mathbf{r}_1)\varphi_2(\mathbf{r}_2)\dots$ with A the antisymmetry operator that changes signs whenever two electrons are permuted, to enforce their Fermi-statistics. This

factorization makes the electrons uncorrelated, which is clearly an oversimplification, but correlations are recovered by linear superpositions of such states that serve as basis functions, and which have been introduced in this form to decide on an explicit form. Two popular choices—tight-binding and Bloch functions—lead to the two main types of excitons: Frenkel and Wannier. With tight-binding functions, the electron remains localized to its atom, as is the case in organic solids where there is weak overlap between lattice sites due to small intersite interactions. Bloch functions, on the other hand, have the periodicity of the crystal built-in as $\varphi_j(\mathbf{r}_j) \equiv u_{\mathbf{k}}(\mathbf{r}_j) \exp(i\mathbf{k}_j \cdot \mathbf{r}_j)$, introducing a momentum $\mathbf{k}_j$ as a label of states and with $u_{\mathbf{k}}(\mathbf{r}_j + \mathbf{R}) = u_{\mathbf{k}}(\mathbf{r}_j)$ for any vector $\mathbf{R}$ connecting two sites of the crystal. They thus delocalize the electron in the solid thanks to the band structure. In both pictures—bound and propagating electrons—the exciton that arises from exciting one electron from any one site, is propagating (i.e., is delocalized), like the Bloch electron. Frenkel and Wannier excitons are thus two limiting models of the same theory, cf. Fig. 1A. The Wannier model is typically valid for low-lying exciton states in semiconductors and crystals with a large dielectric constant. It breaks down for small-radius excitons because first-order corrections are large and hard to calculate, and also because small distances mean a large spread in momentum and thus sensibility to the non-parabolic band structures. A beautiful feature of the Wannier treatment is the natural emergence of Schrödinger's equation for the hydrogen atom for the electron-hole pair. From this, follows straightforwardly the energy of an exciton in a semiconductor crystal as $E_X(\mathbf{k}) = E_{\text{gap}} - R_y + \frac{\hbar k^2}{2m^*} + \dots$ where E_{gap} is the bandgap energy, and R_y is the binding energy. The latter is known from the hydrogen atom as the Rydberg energy $R_y \equiv \frac{e^4 \mu_0}{2\epsilon^2 \hbar^2}$ with $\mu_0 \equiv m_e m_h / (m_e + m_h)$ the reduced mass computed from the electron m_e and hole m_h effective masses. These masses correspond to a quadratic fit to the dispersion relation of the exciton as given by band theory, and can be negatives. This connection to atomic physics is a central manifestation of excitons in crystals, as shown in Fig. 2. The excitonic Bohr radius is also obtained from the atomic theory as $a_B = \frac{\epsilon \hbar^2}{\mu_0 e^2}$. Therefore, one can relate the size of the exciton, as estimated by its Bohr radius, to its binding energy as $R_y = \frac{e^2}{2\epsilon a_B}$, i.e., chiefly through the dielectric constant ϵ , that can vary a lot from one dielectric to the other. The dielectric constant, also called “relative permittivity,” quantifies the polarizability of a dielectric and how this affects the Coulomb force between two point charges in the medium as compared to the vacuum. This is frequency dependent, due to retardation effects (the polarization of a material does not follow instantaneously variations of an electric field). This results in phase shifts that make the dielectric constant complex-valued. The short-range interaction is governed by the low frequency limit of the dielectric constant, while the long-range interaction is ruled by its high (optical) frequencies. Since the Coulomb potential is central to the electron-hole interaction, the features of the dielectric constant impact directly the structure of the exciton. For instance, the dielectric constant is typically large in semiconductors, resulting in important screening of the interaction and thus a weak binding energy, or, in turn, large excitons. Frenkel and Wannier excitons therefore typically occur in small and large dielectric constant materials, respectively, although this admits exceptions. Dimensionality is another crucial factor for the dielectric constant and thus also for the exciton. First Rytova (1967) and Stern (1967), independently, (later, also Keldysh (1979) and others) derived the screened Coulomb potential in two-dimensional structures, featuring a logarithmic shape at short distances and a hyperbolic shape at long distances.

Fig. 2 Optical excitation of an exciton in the semiconductor cuprous oxide: the spectral lines are observed in the bandgap due to the negative (binding) energy of the excitonic states. In (A), as first observed by Gross (1956) (up to $n = 8$) and in (B), as best observed by the Manfred Bayer group (Kazimierzczuk et al., 2014) with very-high (Rydberg) exciton states (up to $n = 25$). The same material, Cu_2O , shows the impressive progress of technology in the course of a half-century. (A) From Gross EF (1956) Optical spectrum of excitons in the crystal lattice. *Il Nuovo Cimento* 3:672, <https://doi.org/10.1007/BF02746069>. Panel (B) is reproduced with permission from Kazimierzczuk T, Fröhlich D, Scheel S, Stolz H, and Bayer M (2014) Giant Rydberg excitons in the copper oxide Cu_2O . *Nature* 514:343.

In one-dimension, one can encounter large-radius excitons with large binding energies, i.e., of a mixed Frankel–Wannier character, due to the shape of the Coulomb potential in such a case (large dielectric constant but small screening). Another potential of note was introduced by Haken (1956), to describe the electron-hole interaction screening in an oscillating lattice, which occurs with phonon vibrations. This results in a distance-dependent dielectric function. In all cases, the binding energy also quantifies the exciton's stability with temperature, up to $T \approx R_y/k_B$ (through Boltzmann constant). The hydrogenic theory also provides a suitable framework to study excitonic responses to applied external fields, in particular through perturbation methods. Understood as huge atoms, one can indeed account for a wealth of properties of excitons that are well-known from atomic physics, such as their easy ionization (with relatively weak electric field as compared to hydrogen), or, before this happens, the Stark effect (shift of the spectral lines under an applied electric field) that is observed with hundreds of volts only, or the diamagnetic effect, Zeeman splitting, Landau levels, etc. Most of these observations have been made in the early years of the field, mainly by Gross (1962) and coworkers (in particular, Zakharchenya) in the wake of their observation of the spectral structure. Littlewood (2022) provides a more detailed exposition of the theory of excitons in this volume.

Excitons in various materials

Excitons appear in solids of various types: in molecular, ionic (particularly the alkali halides), and semiconductor crystals, and in complicated organic compounds. Excitons are too-short lived in most metals to be observable but they occur in superconductors. They have also been observed in some liquids, and even in living matter, where their migration is believed to be an important mechanism of energy transport for photochemical reactions such as photosynthesis. At a more basic level, exciton generation, diffusion, and annihilation are known to be involved in the efficiency of photovoltaic solar cells, although processes there are typically too complex to be described in these terms. It is definitely in crystals that excitons are currently the best understood and the most actively studied. Common properties are found in all cases which can be seen as those defining the exciton (such as the hydrogenoid spectrum $-R_y/n^2$ for Wannier excitons). Still, the details of each solid make their corresponding excitons be sui generis objects. We now give a broad overview of how various materials give rise to various excitons (cf. Fig. 3).

One crystal of choice for excitons is the one in which their first compelling observation was made, namely, cuprous oxide, Cu_2O . This is one of the main oxide of copper (the other being cupric oxide CuO) through the process $4\text{Cu} + \text{O}_2 \rightarrow 2\text{Cu}_2\text{O}$. This red (sometimes yellowish) semiconductor remains to this day—surprisingly, in its natural form even better than when

Fig. 3 Emblematic materials hosting excitons: Cu_2O , GaAs and MoSe_2 , with comparisons of (A) the bulk crystals (an exfoliated foil for MoSe_2), (B) the crystal structures (a mono-layer as seen from the side and from the top for MoSe_2) and (C) the band structures. For Cu_2O (after Meyer et al. (2013)) and GaAs (after Richard et al. (2004)), the full calculated bandgap is shown along with the parabolic approximation around the Γ point. For a monolayer of MoSe_2 , the experimental band structure is superimposed by Zhang et al. (2014a) to the theoretical prediction, showing a stronger direct bandgap than is calculated. Panels (C) are adapted with permissions from Meyer BK, Polity A, Reppin D, Becker M, Hering P, Kramm B, Klar R, Sander T, Reindl C, Heiliger C, Heinemann M, Müller C, and Ronning C (2013) The Physics of Copper Oxide (Cu_2O). Academic Press, chapter 6. <https://doi.org/10.1016/B978-0-12-396489-2.00006-0> and Zhang Y, Chang T-R, Zhou B, Cui Y-T, Yan H, Liu Z, Schmitt F, Lee J, Moore R, Chen Y, Lin H, Jeng H-T, Mo S-K, Hussain Z, Bansil A, and Shen Z-X (2014) Direct observation of the transition from indirect to direct bandgap in atomically thin epitaxial MoSe_2 . *Nature Nanotechnology* 9:111.

synthesized—the best one to host the cleanest and finest excitonic states, as illustrated in Fig. 2. The highest valence and lowest conduction bands stem from the copper atoms in the 3d and 4s orbitals, respectively. The exciton formed by the corresponding electron and hole provides the so-called “yellow series” with energies around 2.1 eV. The 1s state has a binding energy of order 150 meV. This lowest exciton state in Cu_2O is optically forbidden but becomes activated under a strong magnetic field and has been resolved in this way by Brandt et al. (2007) as an essentially perfect Lorentzian with a linewidth as small as 80 meV, making it the narrowest bulk exciton resonance ever observed.

Excitons have also been extensively studied in III–V semiconductors. Gallium Arsenide (GaAs) is the prototypical conventional semiconductor for exciton physics. Semiconductors with a large dielectric constant have only weakly bound excitons, which can be observed only at cryogenic temperatures. In GaAs, the binding energy of excitons is 4 meV, so they ionize much before room temperature. In contrast, in GaN, the exciton binding energy is as large as 28 meV, which makes this wide bandgap semiconductor material suitable for exciton studies at room temperature. In silicon and germanium, the mass is not as isotropic as in other semiconductors and the band structure is more complex, requiring heavy calculations to derive the experimentally observed binding energies. II–VI materials, such as ZnO, ZnTe and CdSe, feature much higher excitons with binding energy in the range from 50 to 200 meV, so they are stable at room temperature, but such structures come with their own limitations, such as a higher disorder. II–VI semiconductor alloys containing magnetic ions such as Mn^{2+} offer a convenient playground for studies of magneto-excitons and exciton magnetic polarons. Such materials are typically characterized by giant Zeeman splitting of exciton states that would be described by effective exciton g-factors of the order of 50.

Graphene—a single layer of carbon atoms arranged in a two-dimensional honeycomb lattice—pioneered a new era of 2D crystals. Graphene’s dispersion relation becomes linear and its electrons thus behave as Dirac (massless) particles, with conduction and valence bands that touch on the edges of the Brillouin zone, thus making graphene a semimetal (or gapless semiconductor). For this reason, its excitonic features, while existing, are not compelling. Rolled-up version of graphene—carbon nanotubes—can be either metallic or semiconducting depending on how they are rolled. Even when completely metallic, and thus expected to be even less excitonic than graphene, the strong 1D screening can reduce interactions sufficiently so that metallic excitons have been observed in nanotubes by Wang et al. (2007). Semiconductor nanotubes, on the other hand, sustain a rich variety of excitons, characterized by large oscillator strengths. In lower dimension, another allotrope (structural-variation) of carbon—the so-called carbyne—is strongly believed to exist in the form of a linear carbon chain of the type $(-\text{C} \equiv \text{C}-)_{\infty}$. Partial chains of this type stabilized at their ends, known as polynes, are well established and have been shown by Kutrovskaia et al. (2020) to exhibit sharp excitonic features at low temperatures. In the wake of graphene, material physics developed other similar two-dimensional crystals that are semiconductors, such as hexagonal boron nitride (hBN, known as “white graphene”), molybdenum disulfide (MoS_2), 2D tungsten disulfide (WS_2), tungsten diselenide (WSe_2), molybdenum diselenide (MoSe_2) and many other dichalcogenides and layered oxides. Their excitonic properties are particularly important since 2D crystals are more stable when they are insulators or semiconductors. Transition metal dichalcogenides (TMDs or TMDCs) are those with the chemical formula MX_2 with M an atom from the transition metal family, in particular Mo (Molybdenum) or W (Tungsten), while X is a chalcogen, i.e., an atom from the group 16 of the periodic table, which is that of oxygen, but, for TMD, with X = S (Sulfur), SE (Selenium) or Te (Tellurium). While bulk versions of these materials are indirect bandgap semiconductors, atomically thin layers acquire a direct bandgap in the near-infrared and visible regions, so of great interest for opto-electronics. This is shown from calculations reported by Splendiani et al. (2010) in Fig. 1B and was established with spectroscopy by Mak et al. (2010). These materials also have exceptionally strong electron-hole Coulomb interactions, with record-value binding energy on the order of several hundreds of meV, thanks again to the reduced screening of the Coulomb interaction in 2D, that also manifests in its excited or charged states. This makes their exciton stable at room temperature. While they are of the Wannier type, their huge binding energy is more characteristic of Frenkel excitons. They also have energy-degenerate band edges at the $\pm K$ points, at the corners of the Brillouin zone, resulting in several extrema of the band structure, known as “valleys,” whose occupation result in “valley excitons” (cf. Fig. 1G), which differ substantially from excitons in conventional semiconductors whose bandgap is at the center of the Brillouin zone (Γ point). To start with, they come with a large variety of bright and dark configurations, especially when also combining valleys with the electron and hole spins. Optical transitions come with new selection rules, with each circular polarization coupling to one valley ($+K$ to σ^+ and $-K$ to σ^-) allowing to easily address each valley by polarization. A strong spin-orbit interaction produces spin splitting of several hundred meV in the valence band and of a few meV only in the conduction band. Valley excitons also behave differently under applied external fields and present great technological prospects. The lowest energy bright valley exciton (known as the “A exciton”), is accompanied by an higher-energy, shorter-lifetime version (the “B exciton”), with the hole residing in the higher energy spin-split valence band, and that decays non-radiatively to the A exciton. There is also a rich collection of charged excitons from the various possible combinations in the valley and split-bands. These valley excitons additionally feature a strong fine-structure due to the exchange interactions between the valleys. While their characterization is complicated, there are also more tools to do so, e.g., polarization-resolved pump-probe and spectral hole-burning measurements.

Spin structure

The exciton spin state is given by the spin of its constituents: electrons and holes. Being fermions, electrons and holes have semi-integer spins that add up to integer numbers, so that excitons should be bosons according to the spin-statistics theorem. The spin projections of electrons and holes onto the crystal axis are not necessarily $+\frac{1}{2}$ and $-\frac{1}{2}$. As an example, in Zincblende

(two interpenetrating face-centered-cubic lattices) semiconductors such as GaAs or CdTe, the valence band is two-fold degenerate with branches characterized by spin (strictly speaking, an effective spin comprising also the angular momentum) projections of $\pm\frac{3}{2}$, referred to as heavy holes, and $\pm\frac{1}{2}$, referred to as light holes. In quantum wells, the degeneracy of the valence band is lifted, and the lowest-energy exciton state is formed by a heavy hole and an electron. Heavy-hole excitons are characterized by four possible spin projections on the structure axis: -2 , -1 , $+1$ and $+2$. Momentum selection rules only enable exciton states with ± 1 spin projections to emit or absorb photons, which are known as *bright excitons*, cf. Fig. 1F. In contrast, ± 2 excitons cannot be directly excited by light and they cannot recombine by emitting a single photon. These optically inactive excitons are thus referred to as *dark excitons*. They play an important albeit implicit role, by interacting with optically active or bright excitons. Spin-orbit interactions for excitons are prominent for the understanding of their optical properties. They stem from two origins: (1) spin orbit interactions for the constituent electrons and holes, such as Eliot-Yaffet, Dyakonov-Perel' and Bir-Aronov-Pikus mechanisms and (2) short- and long-range exchange interactions, which result in the specific fine structure of exciton energy spectra. The longitudinal-transverse (LT) splitting—which is the splitting between exciton resonances in the absorption spectra of light polarized parallel and perpendicular to the in-plane component of the exciton wavevector, in-plane of the quantum well—is caused by the long-range electron-hole exchange interaction. LT-splitting is at the origin of the Maialle-Sham mechanism of spin relaxation for excitons (published by Maialle et al. (1993)), that is similar to the Dyakonov-Perel' spin relaxation mechanism for electrons.

Optical properties of solids

The most important properties of the most common type of excitons arise from their link to light absorption (creating excitons) and emission (when excitons recombine), thus connecting electrical excitations inside the crystal to photons outside, cf. Fig. 3A. This admits exceptions as excitons can also be formed by electrical injection of electrons and holes, e.g., as implemented by Schneider et al. (2013) to realize an electrically pumped exciton-polariton laser. Nevertheless, excitons play a predominant role in the optical properties of solids. Optical methods are also the most appropriate to study them. The most common form of characterization of excitons is found in the absorption and reflection spectra of insulating crystals. The case of semiconductors is particularly important, due to their rich physics and technological importance. Another successful method for characterizing the excited states of excitons is to create them with photons of energy greater than that of the energy gap and to measure the far-infrared absorption due to direct transitions between excitonic levels. A third experimental technique is to detect the luminescence emitted when the photo-produced exciton recombines. The system can also be probed by two-photon excitation, in which case, not the ground state $1s$ but the excited $2p$ couples to light. This allows, among other things, to measure the excitonic energy spectrum and thus to get an estimate of the binding energy. In regions of no absorption, the semi-classical theory of radiation conveniently describes the optical response due to excitons through the dielectric constant of the crystal. In regions of absorption, the quasi-particle picture is favored. In semiconductors with a small binding energy, excitons are the main mechanism of light emission and absorption, although at low temperature only, since at higher temperature, they are not bound anymore and form a plasma of electrons and holes instead. At low-enough temperature, the hydrogen-like spectrum of absorption is observed just below the band gap, which is itself easily identified as an edge in the absorption spectrum. Optical properties are strongly dependent on dimensionality. In bulk, the exciton absorption lines are asymmetric with a characteristic Fano lineshape, described by Toyozawa (1958), which is typical whenever a discrete state (here the exciton) interacts or interferes with a continuum (here optical phonons). The total energy of the exciton is determined by the band-gap energy, the binding energy and the kinetic energy due to its center-of-mass motion. Photoluminescence (PL) can provide information on all these aspects, allowing in particular to extract the distribution of excitons velocity. In 2D, in the absence of excitonic effects, direct band to-band transitions exhibit a step function spectrum that echoes the energy-independent density of states, but in the presence of excitons, the sharp hydrogenoid resonances are observed on top of this structure. In many instances, excitons can also be controlled optically through the quantum coherent phenomenon of Rabi oscillations, i.e., the hermitian cycling that alternates stimulated emission by the exciton of a photon and the reverse absorption of the photon by the exciton. Controlled pulses thus allow to prepare the exciton in a deterministic quantum state, such as a full exciton or a quantum superposition with its ground state. In fact, such coherent light-matter processes are inherent to excitons and give rise to a whole chapter of excitonic physics: polaritonics.

Exciton-polaritons

Just like a self-consistent theory of the electron demands the electromagnetic field (for gauge invariance) and thus its interaction with light, a theory of the exciton cannot dispense from the electromagnetic field. Hopfield (1958) pointed out that the semiclassical description of light absorption by excitons is not “completely satisfactory,” in contrast to absorption due to interband transitions for instance, because of strong photon-exciton coupling phenomena. These were referred to as “light-excitons” in the soviet literature but Hopfield christened them “polaritons” instead, as a general phenomenon of coupling light with a polarization field, that is not limited to excitons (e.g., optical phonons also provide a polarization field for light). This polaritonic effect implies that in bulk semiconductors, excitons actually impede luminescence and radiation, by trapping light into cyclic (Rabi) oscillations with the excitons (Fig. 1J), which breaks only at the surface so that in an infinite crystal, excitons are non-radiative. Similarly, light is not absorbed by excitons but converted into exciton-polaritons, so that true absorption is the result of other mechanisms, such as exciton-phonon scattering, in the absence of which light would be reflected or transmitted. Quantum mechanics also makes the

exciton-photon coupling relevant even in absence of photons. In particular, the polariton vacuum is not the crystal vacuum. At the heart of such polaritonic effects lies the one-to-one coupling of the modes (electromagnetic and excitonic), so that in a system of reduced dimensionality, luminescence is indeed dominated by free excitons, as shown by Weisbuch et al. (1981). This results from a Wigner-Weisskopf dissipation of one exciton to a continuum of photon modes. To restore strong coupling, one must embed the lower-dimensional crystal in a microcavity that also reduces the dimensionality for photons. This gives rise to cavity-polaritons, that are half-light/half-matter quasi-particles combining the electronic properties of the exciton (strong interactions, large mass, ...) and the ultrafast ones of the photon (high coherence, small mass, ...). This new brand of quasi-particles has been revealed in optical experiments by Weisbuch et al. (1992) in two dimensions, by Tartakovskii et al. (1998) in one dimension and by Yoshie et al. (2004) and Reithmaier et al. (2004) in zero dimension. Unlike bulk polaritons—that are tricky to monitor, let alone controlled, due to their dynamics being buried inside the material until they reach its borders—cavity polaritons can be conveniently and continuously monitored thanks to the leakage of the photon from the cavity. A typical degree of freedom in such systems is the exciton/photon fraction of the polaritons, quantified by the Hopfield coefficients that act as a probability amplitude for the quantum superposition between the photon and the exciton. This can be tuned by matching the dispersions of the two modes, so that the excitation can be smoothly changed from one extreme (exciton) to the other (photon) passing by equal superpositions. Even at resonance, where the admixture is half-light, half-matter, different excitation schemes can yield exciton-like or photon-like polariton dynamics in dissipative systems. This results in qualitative differences of their luminescence from a coupled-oscillator model, that otherwise simply links the splitting of the lines to the Rabi coupling, as discussed by Laussy et al. (2008). Thanks to their even more strongly driven-dissipative character, polaritons have rapidly grown from an annex of exciton physics to rapidly expanding and independent research fields, which are overviewed by Kavokin et al. (2017) and discussed in more details in this volume by Litinskaya (2022).

Excitons interactions

Excitons interactions concern the problem of an exciton in presence of other particles or quasi-particles, either other excitons, in which case one deals with self-interactions, or with other types, such as photons (as discussed previously), electrons, holes, phonons, plasmons, etc. Excitons can also interact with (scatter off) defects. Each interaction constitutes a field of research on its own. The basic picture of quasi-particles allows one to embrace the main ideas at a glance.

The exciton-phonon interaction is both important and enlightening as a particular case. It involves the exciton in the more basic problem of electron-phonon coupling, which can itself be described by a variety of models. Prominent electron-phonon Hamiltonians include the Fröhlich and the Holstein Hamiltonians. Exciton-phonon scattering amplitudes can be computed from them with Fermi's golden rule applied to the corresponding exciton-phonon matrix elements. Physically, the presence of an exciton modifies the charge configuration within the crystal by shifting the equilibrium positions of the lattice ions, which gives rise to a coupling between excitons and lattice phonons. Depending on the type of phonons, the interaction can be short range (acoustic phonons) or long range (optical phonons). When such interactions are very strong, and when the hole and electron are greatly separated, they may polarize the lattice individually, the result being a polaron bound to a hole-polaron (the polaron itself being the particle that arises from strong electron-phonon coupling). The "*exciton-polaron*," on the other hand, refers to strong electron-exciton coupling. Strong phonon-exciton coupling can also cause self-trapping, whereby small-radius excitons are clouded by phonons which impede their ability to move. Phonons are affecting a broad range, if not all of the excitonic behaviors, including their energy, oscillator strength, lifetime, coherence, relaxation dynamics, diffusion, luminescence and spectral shapes. In all cases, this can be identified by a temperature dependence. Phonons also open a new (so-called non-radiative) decay channel, which increases with temperature and also causes broadening of the spectral lines. The other way around, phonons are also required to bind an exciton from a pre-existing free hole and free electron, to conserve energy and momentum. They also couple bright and dark excitons. Ab initio Bethe-Salpeter calculations by Marini (2008) in two-limiting cases of weak (in bulk silicon) and strong (in hexagonal Boron nitride) exciton-phonon coupling reproduced accurately the thermal properties of these systems, and found that phonons cause substantial changes even at zero temperatures, such as renormalization (weakening) of their binding energy. Joint incoherent contributions—with independent interactions from the electron and hole of the exciton with the lattice vibration, dominant at weak coupling—and coherent ones—affecting the exciton as a whole and in particular contributing to its buildup at stronger coupling—were identified. Also, a microscopic mechanism for bright and dark excitons transitions was found, based on a transfer of optical strength between energetically-close excitons. Overall, such successful simulations of the excitons-phonons interactions show both their variety and importance in realistic systems, even at low temperatures. Other approaches, for instance based on a master equation formalism, have similarly captured counter-intuitive results and qualitative departures of excitons from atomic systems due to their solid-state environment and coupling to phonons, such as McCutcheon and Nazir (2013)'s finding of an increased quantum coherence due to thermalization of the dressed states.

If there is one basic problem for which the hydrogen body of knowledge brought little insights when applied to its excitonic version, this is the fundamental one of exciton self-interactions. The similarity of the masses of all particles is a first departure from the hydrogen atom. The delocalization of the exciton throughout the crystal, i.e., involving all electrons and holes, is another crucial difference that makes two excitons intrinsically overlapping even when neglecting their interactions, which is the existential problem of cobosons previously discussed. For 1s excitons, since they are electrically neutral, their Coulomb interaction is small, even though largely separated excitons can experience a van der Waals interaction. Exciton interactions become notable when the two excitons get in close proximity to each other. In this case, exchange interactions of the constituent electron and hole become

dominant while the direct Coulomb interaction remains small. The exchange interaction is due to the antisymmetry of the fermionic wavefunction, that tends to push particles apart, as opposed to bosonic symmetry that produces an attraction. The simplest, because the most familiar, and for this reason also the most popular treatment of exciton-exciton interactions is through their bosonization, in which case they are assumed to be structureless (ideal) bosons. Although this procedure, introduced by Hanamura (1974) and others, is still of unclear accuracy or even validity, it appears to provide satisfying result to account for a wealth of experimental results. These include a blueshift of the exciton energy with increasing excitation, a saturation of the oscillator strength as well as collisional broadening, or homogeneous increase of the linewidth. Ciuti et al. (1998) computed scattering strengths (in 2D as befits quantum wells) taking into account the exchange terms, which are the dominant ones. Besides, they differ qualitatively from the direct Coulomb term, being maximum ($\approx 6E_B a_B^2/S$ with S the surface area) for no-exchanged momentum while the Coulomb interaction vanishes in this case. Spin also plays an important role in exciton interactions, with possible scatterings into dark states. Depending on the relative spin, both attraction and repulsion between excitons are possible. Excitons with different spins are distinguishable and thus the dominant exchange terms do not apply to them. In this case, another strong channel of scattering involves the bound state known as biexciton, which we discuss next. While the problem of exciton interactions in its full generality remains a complex area of hotly disputed research, basic consequences such as bound states have gained wide recognition.

Multiexcitons

When several excitons bind together, they form a multiexciton (cf. Fig. 11). The most popular multiexciton is the biexciton, the quasiparticle composed of two electrons and two holes and that constitutes the solid counterpart of a molecule (Fig. 1H). This complex may be stable thanks to the dipole-dipole attraction of two excitons polarized in opposite directions. The spin structure of the constituent electrons and holes is thus essential in this formation. Usually, only singlet states formed by excitons with opposite spins are stable. This imposes a polarization selection rule: biexcitons cannot be directly optically excited by a circularly polarized light as it would only generate excitons with parallel spins that repel each other because of the exchange interaction. In contrast, biexcitons can be excited by a linearly polarized light capable of generating excitons with opposite spins. As the excitation of each biexciton requires two photons, the probability of their generation increases quadratically with the intensity of pumping light, which is a typical signature of their formation. The two-photon excitation energy should be lower than that of two unbound excitons due to their binding energy and spin interactions (higher if these turn out, for structural reasons, to exceed two-excitons energy). Other complexes exist. Trions consist of positively or negatively charged excitons composed by two holes and one electron or two electrons and one hole, respectively. They can be excited in doped semiconductor structures containing residual electrons or holes: an optically excited electron-hole pair binds itself to a residual carrier giving rise to the trion formation. Trion binding energies in bulk semiconductors are usually very small because of the little effective mass imbalance between electrons and holes. In quantum confined structures, such as quantum wells, wires and dots, trions gain a sizeable binding energy and oscillator strength. They can be observed as distinct low-energy satellites to excitonic peaks in absorption or photoluminescence spectra. Quatrons are exotic four-particle complexes with an electric charge of $\pm 2e$ that can occur in a variety of contexts, typically as a doubly charged exciton in a quantum dot. As an example of a particular specie of quatrons, the *Suris tetron* appears at intermediate concentration ranges in the two-dimensional electron-gas between the exciton-trion dominated regime at lower densities and the Fermi-sea at higher ones, with the binding of a hole to a trion, as identified by Koudinov et al. (2014). They can also be understood as trions repulsing the electron gas.

Excitons in heterostructures

Excitons are even more important in systems of reduced dimensionality. These are possible thanks to the concept of heterostructure, that arose from the idea of forming an artificial lattice by alternating layers of two (or more) materials. Initially, this was to improve mechanical properties but the idea proved to be even more fruitful for electronic properties. In the limiting cases of a few layers, such “superlattices” result in a quantum confinement of the carriers and thus, in the case of semiconductors, of the excitons. This opens fascinating chapters of exciton physics in systems of reduced dimensionality, from 2D-excitons in Quantum Wells (QWs) to completely frozen excitons in Quantum Dots (QDs), passing by 1D-excitons in Quantum Wires. For a long time, such semiconductor heterostructures were mainly obtained by epitaxial growth. A more recent but increasingly popular type of heterostructures is that assembled by stacking layers of different 2D crystals. These are known as van der Waals heterostructures, due to the weak interaction between different layers (as opposed to the strong covalent bonds within each 2D layer). This major and fruitful development allowed by a breakthrough in the material physics of semiconductor 2D crystals, revisits the discipline as a whole by allowing an hitherto impossible atomic-level accuracy in the design of crystals, with no constraints from lattice mismatch at the interface. At the crudest level, depositing two flakes of such crystals realizes, by viscoelastic stamping, such an heterostructure. More complex structures are possible, in particular tri-layers, with a large-bandgap material interposed between two active monolayers to further control the recombination rate and dipole moment. Reduced dimensionalities bring a wealth of consequences on the physics of the respective excitons, starting with their density of states. Another immediate and illustrative consequence is the quantum confined Stark effect: applying an electric field perpendicularly to the direction of the exciton confinement does not result in its ionization, as is the case in bulk, since the heterostructure provides a safeguarding confining potential, but modifies instead greatly the exciton’s energy and oscillator strength. This increases drastically the radiative lifetime and produces giant Stark shifts of

the photoluminescence lines. This is due to the electron and hole being pushed in opposite directions by the electric field and thus reducing the overlap of their respective wavefunctions, which quantifies their recombination rate. Similarly to bulk excitons, quantum wire and quantum well excitons feature an energy continuum at the end of their quantized energy spectrum, due to their possible motion through the crystal. QDs are particular in that, by confining all the degrees of freedom, they effectively turn the exciton into a two-level system. Excitons are more relevant in optical QDs, since other types of quantum dots, formed by electrostatic gates, are better described in terms of uncorrelated electronic charges. The physics of excitons in various dimensions is different enough as to be treated independently, which we do in the next sections.

Quantum wells, wires and rings excitons

Excitons emit photons within a radiative zone defined by the conservation of the in-plane or in-wire wavevector between the exciton and the photon, which is defined by a light-cone. Excitons with a larger momentum and thus outside of the light-cone, can be scattered there, by defects, phonons or other excitons, and thus act as a long-lived (non-radiative) reservoir. They also typically act as a background dynamical and spatial potential for the bright excitons. The radiative decay inside the light-cone is very fast, as shown by [Deveaud et al. \(1991\)](#). This led to a thriving field of ultrafast optics in the form of time-resolved photoluminescence. The radiative lifetime is determined by the exciton oscillator strength, and should produce a Lorentzian line (from its exponential decay in time). Other possible decay channels, in particular non-radiative, broaden but otherwise maintain this shape for the spectral line, in which case one speaks of homogeneous broadening. Pure dephasing enters in this category. Other processes can cause an inhomogeneous broadening that results from the emission of excitons of different frequencies, as is typically the case in presence of disorder due to fluctuations of energies in the crystal. This produces, instead, Gaussian lineshapes. Bright trions have different recombination rules than excitons regarding their momentum, since trion recombination leaves the third particle (electron or hole) in the crystal which can absorb the momentum leftover. This process, that still decays exponentially with increasing momentum, produces a characteristic low-energy tail in the trion spectrum.

An auxiliary between 1D and 0D confinement of the exciton can be found with so-called quantum rings (QRs), which close the loop of a wire so as to realize a unique geometry, specific to the solid-state. This makes them appealing for a wide range of problems related to rotational symmetry, discussed by [Fomin \(2014\)](#). QRs attracted special attention in the context of the fundamental problem of the geometric phase, also known as the Berry phase. They are particularly suited for the so-called Aharonov-Bohm effect that describes the geometric phase of a charged particle that goes both ways in a ring bathed in a magnetic field and that interferes with itself when completing the loop. Observable effects from a vector potential that produces no magnetic field are one of the most uncanny features of quantum mechanics and a spectacular manifestation of gauge theory. Excitons are neutral and the effect, first demonstrated with a charged exciton in a ring by [Bayer et al. \(2003\)](#), was thought to be too small for uncharged excitons, which indeed did not evidence it. However, the underlying electron and hole's geometric phases do result in a rich phenomenology for their wavefunction, that does produce an excitonic (also called optical) Aharonov-Bohm effect. This was first noted by [Chaplik \(1995\)](#) as peculiar properties of excitons confined in rings, with a theoretical dependence of their binding energy, effective mass and dispersion on a perpendicularly applied magnetic field. Those have been observed under an applied magnetic flux, first by [Ribeiro et al. \(2004\)](#) as oscillations in PL observables, in so-called type II QDs where the electron is bound by the dot but the hole repelled so as to produce a ring geometry (unlike in type I where both carriers are bound inside the dot), and then, in actual rings, as an oscillator strength periodically changing in time also detected in photoluminescence, by [Teodoro et al. \(2010\)](#).

Quantum Dots excitons

Quantum Dots (QDs) are the ultimate confining crystallite, trapping particles in all three dimensions in systems with sizes ranging from sub-nanometers to small fractions of micrometers and made up from a few thousands only to millions of atomic nuclei. The first quantum dots were reported by [Ekimov and Onushchenko \(1981\)](#) who synthesized nanocrystals of copper chloride in glass, and observed a shift of their excitonic spectral line as a function of the heat-treatment to prepare the crystals, which they interpreted as an effect of size quantization. This was confirmed by [Éfros and Éfros \(1982\)](#) who described the nanocrystallite as a spherical box of varying radius for both one dot and an inhomogeneous ensemble. They also considered various limits of the size, leading to a separate confinement of the electron and hole or of the exciton as a whole. [Éfros \(2022\)](#) provides a detailed account of excitons in nanocrystals in this volume. Several ways have since been found to produce a broad family of QDs. For instance, molecular beam epitaxy can deposit a thin layer of, say, InAs on a GaAs substrate. The strain caused by the lattice constants mismatch lead to the spontaneous and self-assembled formation of little islands of various sizes and shapes depending on the growth conditions. By tailoring the shape, size and composition of the QD, one can tune the excitonic energy spectrum, its interaction energies, Coulomb energies, kinetic energies, electron-hole separations, oscillator strengths, etc. Typically, single QDs from an assembly each present a unique excitation spectrum. If dealing with such a group at large, the specificities of each individual are blurred in the averaging which results in broad emission spectra. Techniques have been developed to isolate single QDs, such as single-dot spectroscopy. This makes QDs rich laboratories to control and study electronic excitations. Such investigations led to describe them as "artificial atoms," in particular for their adherence to the basic atomistic rules of thumb, namely, the "aufbau" (filling-up of successive shells), and Hund's rule (occupying different orbitals of the same energy singly, before alternating spins). These account for how successive excitations get distributed in the energy levels of a QD, as shown in [Fig. 4A](#). When the system fills up with excitons—which is the case under optical excitation—one can in this way witness the successive formation of excitonic atoms

Fig. 4 (A) Charging of multi-exciton states in a single InGaAs Quantum Dot, by [Finley et al. \(2001\)](#). The discrete spectral lines result from excitonic recombinations of states with a well-defined number of electrons and holes, such as X^0 (exciton), $2X^0$ (biexciton), X^{n-} (exciton with n electrons). The charging is here by lowering the applied voltage, which reduces the electrostatic potential of the QD to allow increasing numbers of electrons to tunnel inside (with corresponding thresholds indicated by the dashed horizontal lines), thus not allowing X^{n+} states with n holes, which are also possible in other configurations. The X_p^+ lines at higher energies originate from p -shell transitions. (B) Example of a recombination responsible for the X^{2-} line: while the exciton recombines in the s -shell, it involves electrons in the p shells, (C) In the s -shell alone, in addition to the Ground State (GS), there are 15 possible configurations of excited states, with neutral Bright (BX^0), Dark (DX^0) and bi- ($2X^0$) excitons along with their charged $X^\pm$ versions or isolated electrons and holes. Panel (A) is reproduced with permission from Finley JJ, Fry PW, Ashmore AD, Lemaître A, Tartakovskii AL, Oulton R, Mowbray DJ, Skolnick MS, Hopkinson M, Buckle PD, and Maksym PA (2001) Observation of multicharged excitons and biexcitons in a single InGaAs quantum dot. *Physical Review B* 63:161305(R).

similar to hydrogen (a single exciton in the s shell), helium (two excitons in the s -shell or s^2 in atomic notations), lithium (two excitons in the s -shell, one in the p shell, s^2p), beryllium (s^2p^2), boron (s^2p^3) and carbon (s^2p^4), as described and reported by [Hawrylak \(1999\)](#) and [Bayer et al. \(2000\)](#). When the system fills up with single electrons (or holes)—which is the case under gating or by doping—the single exciton remains the fundamental excitation but gets charged with subsequent excitations and one thus encounters trions $X^{1\pm}$, quatrons $X^{2\pm}$ and higher-still excited states $X^{k\pm}$ with, in the case of [Warburton et al. \(2000\)](#), k up to 5 when completing the p shell. These are referred to collectively as “excitonic complexes” or “multiexcitons.” The respective lines can be identified by a series of signatures, including the order in which they appear and disappear as the QD fills up according to Hund’s rules, the dependence of their intensity on excitation power, e.g., quadratic for biexcitons, their polarization, that is ruled by their spin composition and still other tricks, such as the lack of a fine-structure for the X^{1-} charged exciton that voids its exchange interaction or its large extent in gate voltage. Circular polarizations originate from exciton recombinations while linear polarizations from their quantum superpositions, which can be caused by a fine structure splitting. On the other hand, their distribution in energy indicates, e.g., whether electron-hole attraction or electron-electron repulsion dominates in the multi-exciton configuration, which can change depending on the lateral spatial extension of the electron and hole wavefunction, as shown by [Finley et al. \(2001\)](#) (cf. [Fig. 4](#)). Quantum Dots thus represent flexible artificial atoms, whose properties, although reminiscent of real atoms, can greatly vary in both qualitative and quantitative ways. For instance, the number of p and higher (d , etc.) shells thus becomes restricted to 2 in case of in-plane confinement for QD with cylindrical symmetry, as opposed to 3, 5, etc., for real (3D) atoms. There is also typically an asymmetry of QDs formed by interface fluctuations, which results in elongated shapes which further lift the degeneracy

of these states, resulting in a fine-structure splitting between them with polarized emission (those grown by colloidal chemistry, on the other hand, have a much greater spherical symmetry). Quantum dots are nowadays highly controlled both experimentally and theoretically. The fine-structure of their excitons is particularly well understood, with Bayer et al. (2002) taking into account spin interactions, such as the exchange Coulomb interaction, as well as hyperfine interactions with the nuclear spin from host atoms in the lattice, and the Zeeman interaction with an applied magnetic field. Rabi oscillations of QDs excitons have been first observed by Stievater et al. (2001) and demonstrated the validity of single excitons to realize the quantum optical physics of atoms, with π -optical pulse that revert their state, i.e., preparing the exciton in the one-particle state or, if already present, returning the system to the crystal vacuum by stimulated emission. The Rabi flopping could later be observed by Ramsay et al. (2010) for over 14 π -pulses with a dephasing due to LA phonons and with a renormalization of the Rabi frequency attributed to fluctuations in the phonon bath, making the effect a solid-state analogue of the QED Lamb-shift for the hydrogen atom in vacuum. Related quantum optical milestones, such as the Mollow triplet of resonance fluorescence—where the exciton forms a quantum superposition with the laser photons to produce a ladder of equally-spaced dressed states—have also been unambiguously reported, for instance by Flagg et al. (2009).

Direct and indirect excitons

Heterostructures allow to design complex arrangements of the confining potentials which permit to design sophisticated trapping for the electrons and holes, giving rise to new types of excitons, for instance by separating spatially their electron and hole. One can thereby grow two QWs (a so-called double QW) side to side and apply an electric field normal to their plane, forcing the electron in one well and the hole in the other (cf. Fig. 1C). Their binding across the barrier that separates the two wells leads to a spatially “Indirect Exciton,” denoted as IX. Same-well excitons are still possible and become known, in contrast, as spatially *Direct Excitons* (DX). The qualification of “spatial” is added if there is the need to distinguish from excitons in direct and indirect bandgap materials, where the separation is in momentum instead of in real space, and with the same consequence of decoupling the excitons from direct photon recombination/excitation, requiring, e.g., phonons to assist in the process (Fig. 1B). Recombination of IX is also possible, by tunnelling through the barrier, but is strongly reduced as compared to the DX one, as indeed the wavefunctions are spatially separated and their overlap becomes much smaller. This increases considerably their lifetime, by several orders of magnitudes in GaAs structures which can thus span over ns to tens of μ s as compared to few ps only for direct excitons. Another advantage of IX is their strong-dipole moment ed aligned perpendicularly to the QW, with d the distance between the electron and hole layers (for this reason, they are also called “dipolar excitons”). Applying an electric field perpendicular to the QW plane results in an IX energy shift, known as the quantum confined Stark effect, and varying this field in space allows to create highly-tunable potential landscapes, of various shapes and extent, that can be static or dynamic. A diamond-shaped trap, for instance, allows to create a parabolic potential, which collects excitons and trap them at the center. One can thus apply a force through an electric field for these otherwise neutral particles, through a gradient of the field that turns into a gradient of energy shifts for the indirect excitons. Strong dipole moments also result in dipolar interactions that are stronger than the exchange interaction of direct excitons, and also of a long-range character $\propto 1/r^3$ at large separations. Their repulsive character of oriented electric dipoles make them more stable against bound states or condensed phases. Indeed, the dipole polarization of excitons is not random but is imposed by the structure geometry and dipole-dipole repulsion prevents the formation of biexcitons. The same idea also applies to excitons in van der Waals heterostructures, as demonstrated by Rivera et al. (2018) (cf. Fig. 1D), with the advantage of a much enlarged space of parameters and with better control of the crystals. In that case, although the concepts and consequences are the same, one commonly speaks of “interlayer exciton” (ILX) instead of indirect ones. Besides, in addition of being spatially indirect, ILX can also be momentum-indirect, with the electron located in the K valley while the hole is located at the T point, as shown by Kunstmann et al. (2018). Quantum dots, as artificial atoms, can in a similar way be designed to form quantum dot molecules (QDMs), for instance by stacking two quantum dots on top of each other, as done by Schedelbeck et al. (1997). The exciton can now be formed by having its electron in one QD and its hole in the other, also producing an indirect exciton which, in a QD, becomes a solid-state counterpart of the H_2^+ hydrogen molecule with one electron orbiting two protons, with the formation of bonding and antibonding states from the coherent excitonic wavefunction delocalized over the two QDs. The photoluminescence of QDM is markedly different from its single (atomic) QD counterpart: in addition to single lines indicating the multi-excitonic states, a rich phenomenology of crossing and anticrossing patterns emerge, involving states with much larger electric field dependencies thereby producing lines with very different slopes in the PL spectra as a function of the applied electric field. These are due to the strong Stark shift enabled by indirect excitons. The coupling of excitons and biexcitons, both inter and intra QDs, give rise to a characteristic X patterns, studied by Stinaff et al. (2006) and Scheibner et al. (2007), that are observed when the initial and final states undergo level resonances at similar electric fields.

Key issues and trending topics

Rydberg excitons

Rydberg atoms are atoms whose outermost electron is excited in a quantum state $|nlm\rangle$ with a high principal quantum number n . Since the effective size of the atom grows with n as $\frac{1}{2}a_B(3n^2 - l(l+1))$, Rydberg atoms are huge atoms with a correspondingly large dipole moment and thus a strong response to external fields as well as strong interactions. This makes them valuable for a wealth of

applications, such as their minute control in quantum optical experiments (leading to the 2012 Nobel prize, for “measuring and manipulation of individual quantum systems”). For the Rydberg exciton counterpart, a large binding energy is required, so that high values of n can be reached. From thermal dissociation alone, since the binding energy of the n shell scales like n^{-2} , the highest possible n is of the order of $\sqrt{\frac{E_B}{k_B T}}$ which is about 6 for GaAs while it is close to 30 for Cu_2O , which is the material where Rydberg excitons are currently flourishing. Bringing excitons into a Rydberg state, as demonstrated by Kazimierzczuk et al. (2014) and shown in Fig. 2, is another compelling demonstration of their status of solid-state atoms. Low-level Wannier excitons being already large, their Rydberg version becomes gigantic, extending to Bohr radii as large as several micrometers, that is to say, over billions of sites of the lattice, for what remains a two-particle wavefunction. Despite stressing the excitonic picture of a bound state inside its host crystal to the limit, observations adhere remarkably well to relatively simple theoretical modellings. For instance, deviations from a pure Coulomb potential (such as is caused by the screening from inner electrons) can be taken into account through a so-called quantum defect δ that renormalizes the hydrogenoid spectrum as $E_n = -R_y/(n - \delta)^2$. Rydberg excitons allow a detailed study of fundamental atomic effects, in particular of scaling properties: not only the size of the state but other characteristic properties scale with power-law dependencies on the principal quantum number, as studied in details by Heckötter et al. (2017). These include the binding energy (like n^{-2}), the linewidth and the oscillator strength (n^{-3}), leading to ultra-sharp resonances, and still other observables, such as the van der Waals interactions, scaling as n^{11} and thus producing a huge nonlinear absorption, referred to as Rydberg blockade, as per the blockade mechanism whereby the presence of one excited state prohibits the excitation of other states by direct repulsion. Furthermore, although of mesoscopic sizes and in a highly excited state, Rydberg excitons are believed to retain their quantum coherence, as was discussed by Grünwald et al. (2016). Rydberg excitons are therefore currently at one forefront of research into quantum-optical and exotic condensed-matter effects and could enjoy in the solid state the same fruitful path as their vacuum counterparts in a breadth of applications.

Excitons in quantum Hall bilayers

An exotic breed of excitons consists in pairing, not an electron with a hole, but two electrons, in so-called electron bilayers, that are similar to the coupled QWs used for IX but such that both wells have conduction electrons and using a magnetic field instead of an electric one. This allows to bring the physics of Landau levels: the quantization of the electron cyclotron orbits under the applied magnetic field produces equally-spaced energy levels (the Landau levels) which are degenerate with a number of electrons per level proportional to the strength of the magnetic field. Each layer in isolation at half-filling of the lowest Landau level, constitutes a compressible Fermi liquid that behaves as a nonquantized Hall phase. Their pairing gives rise to new physics. Similarly to missing electrons in the valence band being treated as hole quasi-particles, an empty state for the Landau levels becomes an anti-particle with opposite charge. The fraction of occupied Landau levels, known as the filling factor, is tunable with the magnetic field. It is, in particular, possible to equate the number of electrons and holes, in which case one gets a counterpart of the standard “optical excitons.” Since such Landau levels are at the heart of the quantum Hall effect, the structures hosting such excitons are known as quantum Hall bilayers and the reliance on the magnetic field also brands their excitations as *magneto-excitons*. An immediate obvious advantage of the bilayer electrons, is that the excitons they form are stable: they do not recombine. They can therefore reach a true equilibrium with no race for thermalization against their finite lifetime, which is the main limitation for exciton thermodynamics.

Excitonic matter

Once one recognizes that the excitonic picture of an effective hydrogen-like quasi-particle wandering freely within the crystal is valid, or at least useful, the next step is to keep on pushing the analogy and inquire whether condensed phases of excitons are possible, even though these would arise from quasi-particles of a more fundamental condensed system in the first place. The meta-analogy will be complete when one reaches the exciton state of excitonic matter itself. Interestingly, such questions have been entertained from the earliest days of excitonic physics, but remain among the most trendy and fundamental ones to this day. We now survey the most popular excitonic phases, starting with classical ones. The simplest is the gaseous phase, in the most extreme case of which excitons are assumed to be independent from each others, which, if at all possible, is to be sought at low densities. By sending laser pulses on a crystal and making snapshot of its luminescence (from exciton recombination) at different intervals, it has been possible to evidence clearly the drift of an exciton gas, accordingly to the kinetic theory of (normal) gases, in particular with the correct distribution of their velocities, with a temperature given by the lattice and a very large diffusion coefficient as mandated by the low exciton mass. Low-density excitons therefore qualify as a gas of particles confined inside the solid. Their mobility is considerably higher than even other solid-state particles, like electrons. Excitons have been shown by Tamor and Wolfe (1980) to drift under applied strain at speeds exceeding several hundred meters per seconds (as opposed to a few millimeters per seconds for an electron) over distances of several millimeters (cf. Fig. 5A). The strain is applied mechanically and causes a change of the bandgap, in turn resulting in a force applied to the exciton, which can be tracked by photoluminescence. To evolve from the dilute gas picture of excitons to more strongly correlated phases, one can simply increase the optical power to create more excitons. Doing so, one should not reach densities so high that excitons ionize into an electron and hole plasma, a process known as the Mott (1968) transition. Indeed distinct from a condensed phase of excitons, electron-hole liquids have long been known to exist but they arise when excitons themselves have been destroyed, or ionized, and thus, although interesting for their own sake, do not count as excitonic matter. A proper excitonic liquid can still be formed by the strong repulsive dipolar interaction between indirect excitons.

Fig. 5 Two phases of excitonic matter: (A) drift of an exciton gas in Cu_2O , photographed by Trauernicht, Wolfe and Mysyrowicz (1984), showing how excitons created by a green laser (left) drift and recombine (red glow) in the minimum of a potential stress induced by pressure exerted on top of the 3D crystal, (B) At higher densities, indirect-excitons in 2D quantum wells, imaged by Butov et al. (2002) in-plane of the well, exhibit an unanticipated ring structure that is fragmented in a highly-ordered way. The laser that drives the system is in the central bright spot, or “inner ring.” The localized bright spots, which unlike the other rings do not follow the laser but remain fixed, are believed to be excitons trapped by defects. These images show how the excitonic picture, compelling in its gaseous phase, displays complex and original phenomenologies beyond expectations in its condensed phase. Panel (A) is reproduced with the permission from Wolfe JP and Mysyrowicz A (1984) Excitonic matter. *Scientific American* 250:98 and (B) from Butov LV, Gossard AC, and Chemla DS (2002) Macroscopically ordered state in an exciton system. *Nature* 418:751.

This is a regime of strong correlations, albeit believed to be of a classical character since it occurs with a negligible overlap of the excitonic wavefunctions. This phase is observed to behave thermodynamically, appearing abruptly below a critical temperature and above a critical density, and, when it is formed, to extend gradually to cover the full sample but with a low diffusivity. It also has a low conductance and its lineshape in PL is Gaussian and narrowing with increasing densities, like a liquid which is strongly correlated at short distances and as opposed to an uncorrelated gas which has a low energy tail characteristic of a fluctuating volume around the excitons. Its coexistence with another phase that matches an electron-hole plasma, reported by Stern et al. (2014), gives a picture of excitonic droplets. In between these droplets, it is believed that one finds a rarefied excitonic gas. After the gaseous and liquid phases, comes the crystalline phase. One has been predicted by Suris (2016) based on a calculated lower free energy for a triangular lattice than for the gaseous state, but in 2D and with long-range repulsive interactions, which is, however, the case for IX. Exciton interactions differing in the two phases, the desublimation (gas to crystal transformation) is predicted to yield strong qualitative signatures, with a clamping of two lines of photoluminescence as the excitonic crystal grows. At higher densities, when the system undergoes its Mott transition, a BCS-like mechanism for excitons has also been theorized by Keldysh and Kopayev (1965), that would also lead to a solid phase. In indirect bandgap semimetals, i.e., with a gap in momentum rather than energy, a spatial symmetry breaking (as opposed to $U(1)$ symmetry breaking in a superconductor) should exhibit perfect conductivity yet with no Meissner effect (expulsion of magnetic field), which has been described as an excitonic solid, the “excitonium,” being also an analogy of a Wigner crystal but for excitons rather than electrons. In all these cases, there is the question whether the phase is classical, with their strong correlations and ordering being alike to solids, or, given the nature of the quasi-particles undergoing the transition, quantum. What constitutes specifically or genuinely quantum effects in such excitonic phases is still highly debated, as is overviewed in the next section.

Exciton BEC and superfluids

Macroscopic quantum phases realized by the solid state and exhibiting exotic effects are not disputed, thanks to their broad range of compelling manifestations. These include superconductivity, superfluidity and Bose-Einstein condensation. Whether quasi-particles themselves can directly undergo such quantum transitions is much more open to debate. Superconductivity gives rise to Cooper pairs, for instance, but whether the superconducting phase itself can be understood as a Bose-Einstein condensate (BEC) of Cooper pairs is not widely agreed upon. The relevance, accuracy or even correctness of such an understanding as applied to any type of quasi-particles leads to many discussions in the literature. Excitons have been among the most hotly disputed quasi-particles to take part in such arguments. This is despite the fact that their delocalized nature throughout the entire lattice makes them intrinsically ideal to exhibit long-range order quantum coherence. While such macroscopic coherence for a single excitation is typically not expected despite being foundational to the theoretical picture, it can in fact be observed as was demonstrated by Dubin et al. (2006) with a single-exciton state—as compared to a dense gas—exhibiting fringes and so coherence at both ends (10 μm apart) of a conjugated polymer chain (that behaves like a quantum wire). Nevertheless, the most basic picture of quantum coherence relies on the coherent teaming of a large assembly of bosons. The Bose statistics of excitons, as well as their diluted hydrogen-like gaseous structure at densities $n \lesssim 1/a_B^D$ in a D -dimensional system, thus make them prime candidates for the phenomenon of Bose condensation. Moskalenko (1962) and Blatt et al. (1962) had considered them as strong contenders much before the first experimental BEC demonstration, which was with cold rubidium atoms in 1995. Such a Bose condensation can be understood as a condensation in momentum space where, consequently, the system becomes delocalized in space into a

macroscopic wavefunction, as opposed to exciton droplets, which are classical condensates in real space. The small effective mass and large Bohr radius of excitons make their critical temperature for 2D BEC $T_c = 2\pi\hbar^2 n / (mk_B)$ a few K for densities of the order of $10 \times 10^{10} \text{ cm}^{-2}$, i.e., well within reach. Strictly speaking, in 2D, not BEC but a related phase transition—the Berezinskii-Kosterlitz-Thouless (BKT) one—describes coherence, which cannot be of infinite extent as it is destroyed by fluctuations, but decays slowly (as a power-law) instead. This is however for ideal systems while a real sample, in addition to be of finite dimensions, presents spatial fluctuations that act as local potentials in which 2D condensation becomes possible. This can be understood most simply by assuming a single potential that quantizes at least the lowest energy levels, or elaborately by considering the density of states of a disordered system that smooths out the 2D ideal case of an abrupt jump, into a 3D-looking one with a smooth vanishing of the state density. Besides, given that excitons have a large spatial extension, the picture of pointlike bosons eventually breaks down at large enough densities and their underlying structure becomes significant, in which case an electron-hole Cooper pairing should occur instead, as hypothesized by Keldysh and Kozlov (1968). In any case, despite favorable conditions from basic estimates, there are many difficulties to achieve exciton condensation. Unlike atoms, the exciton temperature is not directly accessible by direct cooling, only that of the lattice is and excitons are created with vastly larger temperatures, especially at the high densities required for their condensation. Their short radiative lifetime also makes it difficult to reach an equilibrium before excitons have recombined. The ground state of Cu_2O being optically inactive, it was hoped to circumvent this difficulty, but excitonic Auger processes (two-exciton collision annihilating one and transferring excess energy to the other) turned out to have a detrimental density/temperature contribution. To avoid coherence induced by the driving laser and let the system spontaneously form coherence through a spontaneous symmetry breaking, one should also seek signatures under non-resonant excitation, ideally, an electric one. A difficulty in such a case where all types of excitons are allowed, is that dark indirect excitons have typically slightly lower energy than the bright ones, due to the exchange interaction, and so the ground state of the exciton fluid should be dark, thus not directly optically observable, as indeed reported by Cohen et al. (2016). Not least is that even if the phase is actually realized, its unambiguous identification is problematic since a realm of alternative unrelated phenomena can produce a similar phenomenology, e.g., the Peierls phase—a spontaneous crystal distortion driven by the electron-phonon interaction and unrelated to excitons—for Bose condensation or the phonon wind—a drift force imparted by non-equilibrium phonons that push the excitons—pausing for superfluidity of particles with an already high mobility. Indirect excitons overcome several of the main limitations, with an increased lifetime and stronger interactions, added to the relaxation of their momentum conservation perpendicular to the plane that couples them to a continuum and thus speeds up their relaxation as opposed to the one-to-one coupling in bulk. This allows them to reach less than a tenth of the theoretical critical temperature within their lifetime. There are various ways to study the macroscopic quantum coherence of such excitons. To excite them non-resonantly, one can either create an excitonic population with a pulse and let it relax in time, or use continuous excitation but observe them farther apart from the laser spot after they drifted or have been transported there, and cooled down to lattice temperature. In the second scheme, an unexpected ring-structure, centered around the laser spot, with no emission in between, has been observed by Butov et al. (2002) (cf. Fig. 5B) and Snoke et al. (2002). While not apparent in Fig. 5B where the intensity gets saturated by the laser, Butov et al. (2002) actually resolves two kinds of rings: an internal one, which is remote from the laser-excitation spot by a distance comparable with the exciton diffusion length, in addition to the external ring, whose radius grows with increasing pumping power or decreasing applied voltage. This external ring can thus be sent to distances commensurable with the millimeter, away from the excitation spot, validating it as a macroscopic effect. It also exhibits a macroscopic pattern formation, consisting of periodically-spaced exciton bright spots referred to as a “macroscopically ordered exciton state.” This structure is pinned to the excitation laser beam and moves coherently with it if the beam is displaced. The whole structure of rings and spots collapses with increasing temperature into a Gaussian spot around the laser while the macroscopic ordering of bright spots appears below a critical temperature. The interpretation of this phenomenology is as follows: at high-enough density, excitons are freely moving particles, with strong dipolar interactions allowing them to screen potential fluctuations from the sample. Excitons that are moving too fast are beyond the light cone of possible radiative emission and thus do not emit photons. As they cool down, their individual kinetic energy lowers and they become radiative. The interplay of this with the potential landscape of the laser spot explains the inner ring. The outer ring, on the other hand, has been explained by Butov et al. (2004) and Rapaport et al. (2004) as exciton generation at the interface of the electron-rich (n) and hole-rich (p) regions. More intriguing is the periodic ordering displayed by the excitons in the external ring observed by Butov’s group. The periodic pattern has been attributed by Levitov et al. (2005) to a Turing-type of instability as applied to a Bose gas undergoing stimulated scattering. This not only identifies the phenomenon as quantum, unlike the rings and bright spots which can be understood classically, but also shows how exciton condensation exhibits original and unforeseen phenomena not found in any other system. The coherence of these excitons, as well as those from the bright localized spot, was established by High et al. (2012) both through the classic measurement of their first-order correlation function $g^{(1)}(\Delta r)$ as well as from the build-up of polarization, both furthermore occurring together. The degree of coherence is larger on the edges of the spots, suggesting that the ideal density for condensation is not the highest one. The coherence length extends over several microns, so order of magnitudes more than for the classical exciton gas. Such dislocations and their ordering are reminiscent of vortices in superfluids and superconducting phases, and indeed phase dislocations have also been evidenced. However, their connection to the ring itself as opposed to isolated vortices, suggests a more complex and original structure of the excitonic condensate than had been theorized. Shift-interferometry experiments that allow to discriminate between various types of phase dislocations have been used by Leonard et al. (2021) to further support Bose condensation of indirect excitons by evidencing a flow of excitonic matter waves from localized bright spots, producing a moiré effect consistent with the observations. In other structures, similar quantum phases have been claimed. In quantum Hall bilayers, for instance, where lifetime is not an issue and critical densities for condensation can be fine-tuned,

the possible tunnelling of an electron hopping from one layer to the other signals a collective state of excitons, in the form of an ultra-sharp peak in the tunnelling rate for a critical separation between the layers, as was reported by Spielman et al. (2000). Such a peak can be explained as a pairing of electrons and holes in an excitonic, i.e., correlated fashion. Another dramatic observation by Kellogg et al. (2004) is the collapse of the Hall voltage when excitons are formed, as their electrical neutrality does not result in a flow of charge in the structure even though electrons and “holes” (that are also electrons) in both layers are in motion. In absence of their correlations (due to unmatched filling factors or distances between the layers beyond the critical one), two opposite Hall voltage cancel together but exist in each layer. In presence of such correlations, no voltage at all is present. This proves a correlated excitonic motion, as opposed to one of uncorrelated electrons and holes that cancels on average. The same effect was reported with indirect excitons in GaAs by Nandi et al. (2012) where it was described as a perfect Coulomb drag with a flow in on layer correlating a counter-flow in the other thanks to the condensation, and a similar phenomenology was also found with van der Waals semiconductors (MoSe₂-WSe₂), where a hBN barrier was used to suppress radiative recombination from interlayer excitons in the two TMD layers. The observation of a critical threshold for electroluminescence depending only on the exciton density and with a large and narrow peak of its intensity for equal electron and hole densities, also supports an excitonic BEC, from coherent and correlated pairing of the excitons from a condensed phase. While 2D systems have been the focus for the search of excitonic condensation since the early attempts in Cu₂O, it has also been claimed in the 3D indirect bandgap semimetal TiSe₂ by Kogar et al. (2017) with a dedicated momentum-resolved electron energy-loss spectroscopy technique. That allowed them to probe the collective excitations and evidence the Goldstone mode of the excitonic condensate (exciton sound) that thus distinguishes the BEC phase from the Peierls one by exhibiting electronic as opposed to phononic modes. In all these cases, while the evidence is very strong, it still awaits consensual and unambiguous recognition that a BEC of excitons is, not only present, but to which extent, with which characteristics and with what relationships to related quantum phases. The complications of a finite lifetime in a disordered environment have furthermore been theoretically anticipated by Glazov and Suris (2018) to bring other and more surprising conceptual departures from equilibrium systems, such as requiring a finite temperature below which BEC becomes impossible, in contrast to the usual picture that the lower the temperature, the better. Excitonic condensates are thus clearly complicated objects as compared to their atomic counterparts, in a way that the single exciton is not. Although it does not transport neither charge nor mass, exciton superfluidity is another appealing quantum phase. The spectrum of elementary excitations of the excitonic BEC is expected to be linear and thus to adhere to the Landau criterion for superfluidity, by opening a gap for the possible excitations of the system, that is thus resilient to small perturbations, although other models regard the excitonic BEC as insulating.

Emerging trends and future directions

Moiré excitons

A twist made possible with the emerging van der Waals structures is to play with their angular crystallographic alignment, namely, to rotate one plane on top of the other (cf. Fig. 1E), something not possible with conventional crystal growth. This produces moiré patterns that in turn produce periodic and large-scale potentials, i.e., superlattices, with a characteristic wavelength that can range from a few to hundred nanometers. The excitons trapped in these particular landscapes give rise to a new brand of excitons: the moiré excitons, e.g., as reported by Seyler et al. (2019) in MoSe₂/WSe₂ heterobi-layers. Inter-layer excitons are highly sensitive to such an angle, with strong variations of their PL emission, due to electron and holes at different K points having a finite momentum. This makes the corresponding excitons dark with zero momentum but becoming radiative if their exciton has the opposite momentum. This can be set by the angle, which controls the intervalley momentum separation between layers. Moiré excitons also exhibit spatially modulated selection rules for optical transitions with excitons localized at different sites of the moiré lattice and in different valleys emitting different polarizations. Short-range moiré lattices, on the other hand, produce minibands with folding of intra- and inter-layer excitonic bands, resulting in an hybridization between the intra- and interlayer excitons. This was reported by Alexeev et al. (2019) with holes from MoSe₂ binding to a twist-dependent superposition of electron states in the adjacent layers. The moiré potentials can be sufficiently strong to further quantize the trapped excitons, leading to antibunching (time separation) of their photon emission. The variety of phenomena ruled by the angle between the layer is so considerable that a new field of “twistronics” has emerged.

Topological excitons, insulators and superconductors

While BEC and superfluidity have been, and remain, greatly discussed for excitons over several decades, more exotic quantum phases have emerged recently or are gaining increasing attention, especially when linked to the recent developments brought in condensed-matter physics by topology. A central topological phase is the Mott-insulator, describing a crystal that should be a metal according to conventional band theory but which, due to strong Coulomb interactions, behaves as an insulator instead. The simplest model to account for this physics is given by the Bose-Hubbard Hamiltonian, that rules the interplay between on-site interactions of bosons in a lattice and the energy tunnelling between adjacent sites. Such a phase has been already demonstrated with ultracold atoms, and was recently realized with dipolar excitons, in both triangular-lattice of moiré excitons in van der Waals structures (by Tang et al., 2020) and square lattices nano-patterned by metallic electrodes deposited on GaAs bilayers (by Lagoin et al., 2022). The Mott insulator phase consists of a distribution of the excitons to occupy each lattice site with a fixed and identical number of particles. Such non-fluctuating particle numbers are typical of strongly quantum correlated phases, as they break the

normally-distributed fluctuations of most classical systems. In the GaAs case, for instance, two Mott phases with one and two excitons per site, all in the same Wannier state, have been evidenced through spectral observations echoing in the PL the ordering of excitons in the lattice. Another insulating phase, this time directly attributed to excitons—the excitonic insulator—arises when the exciton’s binding energy competes with the bandgap and is thus particularly relevant in semimetals. This phase is now believed to have been observed by Jia et al. (2022) for the first time, in WTe_2 , and to account for another paradigmatic topological phase but for electrons, the quantum spin Hall effect, that locks their momentum to their spin and thus constrains their motion on the edge of the sample in one direction only (preventing back scattering at zero magnetic field). It has also been linked to exciton condensation by Sun et al. (2022). Realizing and controlling such topological phases is important for prospects of harnessing quantum coherent effects, including condensation, superfluidity and superconductivity, as well as for building quantum simulators, that implement in a physical platform a model Hamiltonian that is too awkward to be described theoretically or computationally, but that can be simulated by observing the actual system. This could target topical systems such as high- T_c and d -wave superconductors in other platforms, supersolids, Luttinger liquids, Kitaev models, generalized Kane-Mele model with a topological flat band, interaction-driven Haldane insulator, quantum magnets, Majorana modes, etc. An advantage of excitons as compared to electronic systems, such as graphene, is that optical recombination allows a convenient and precise observation of the underlying physics. Even when excitons themselves do not play the predominant role in such quantum phases, they can be crucial auxiliaries to aid or witness other quasi-particles into their quantum transition, such as for the formation of Wigner crystals (crystal of electrons) where excitons feel the periodic potential from the electrons, that undergo a typical scattering (Umklapp) producing a telltale signature in the form of a resonance. This approach has been exploited by Smoleński et al. (2021).

Among the most topical effects, superconductivity, at first sight, appears to be not relevant for excitons since they are neutral particles. A trion, however, is not, and conventional charge-transport is thus possible in this way, as demonstrated by Sanvitto et al. (2001), while their Bose condensation in a superfluid regime would result in their superconductivity, which was first suggested by Lozovik and Yudson (1976). Indeed, excitonic BEC in bilayers allows a net flow of charge intra-layers while still producing no net electric flow inter-layers if they are of the same magnitude but opposite directions, a mechanism that can be interpreted as “counterflow superconductivity.” Related mechanisms are important for superconductivity of paired electrons, for instance in graphene, but put more emphasis on the underlying constituents than on the excitonic quasi-particle as a whole. Less forthright for exciton superconductivity is a proposal from Ginzburg (1968) and taken-up by Bardeen (1978) himself, the historical figure who understood how phonons mediate superconductivity by pairing electrons into Cooper pairs. Together with Allender et al. (1973), Bardeen considers a bilayer structure, where phonons are to be substituted by excitons, the so-called “exciton mechanism” (of Ginzburg). In Bardeen–Cooper–Schrieffer (BCS) theory, the critical temperature is of the type $k_B T_c = \Theta e^{-1/g}$ with Θ the Debye energy (cutoff energy for a maximum phonon energy) and $g = \mathcal{N}(0)V$ the product of $\mathcal{N}(0)$ the electron density at the Fermi level and V the electron-phonon interaction, which result in the low-temperatures observed in conventional superconductors. One can thus raise T_c by increasing Θ and/or g , which remains marginal with phonons. Substituting for excitonic values, that can produce a much stronger electron-electron attraction even if the retardation effect characteristic of BCS superconductivity is reduced. Taking both competing effects into account, one finds $\Theta/k_B \approx 10^3\text{--}10^4$ K and $g \approx \frac{1}{5}\text{--}\frac{1}{2}$ resulting in critical temperatures of several hundred Kelvin, which pioneered the quest for high-temperature superconductors. At still another level of the same idea, one can mediate Cooper pairing not with excitons which, just as phonon in BCS, are virtual excitations mediating the interaction, but with real excitons present in the system as a condensate, in which case their virtual excitations become those mediating the interaction. Since forming an exciton BEC is difficult, this can be eased by involving polaritons in a microcavity, as proposed by Laussy et al. (2010) or driving the excitonic BEC with a laser, thereby realizing a light-induced superconductivity mediated by excitons, which has also been predicted to possibly reach room temperature. While such effects have not yet been observed, related strongly-correlated quantum phases mediated by light, such as ferromagnetism of excitons, have indeed been realized by Wang et al. (2022) with moiré excitons exhibiting a characteristic hysteresis loop in their magnetic response.

Excitonic devices

Excitonic devices already exist. They will probably invade the market as both technology and theoretical understanding progress and the transition from proof-of-principle demonstrations to a working superior excitonic technology will be achieved. In zero-dimension, quantum dot excitons already power some of the best quantum light sources, both at the single-photon level and for LED or laser applications. For the display industry, they offer high color purity and ultra-high resolution from thin screens, with also excellent brightness and a large color gamut, including perfect black. For lasing, excitons in colloidal quantum dots—that already provide efficient photoluminescence over a wider spectrum than their epitaxial counterpart—have also demonstrated with Dang et al. (2012) single-exciton gain, allowing to implement highly-efficient, low-threshold full-color lasers. For quantum applications, multiplexed (i.e., synchronized) QDs have, among other services, already allowed to claim quantum supremacy in boson sampling. All these feasts follow from the highly-tunable excitonic properties in artificial atoms that can be molded at will in a thriving material physics. The QD exciton that behaves like a two-level system becomes, in quantum mechanical terms, a qubit, i.e., the fundamental unit of quantum information processing which can sustain superpositions of states and nonlocal entanglement, needed for quantum information processing. Coupled excitons in a single QD have been used in this way by Li et al. (2003) to build a two-qubit gate. In a paradigmatic which-way recombination, the biexciton’s decay to its ground state through a radiative cascade passing by one or the other exciton, leads to entanglement of the emitted photons, as shown by Akopian et al. (2006). By quantum-correlating deterministically hundreds of photons—so-called cluster states, able to power universal quantum

computation—the interplay of dark excitons with the biexciton through a precise timing by optical pulses allowed Schwartz et al. (2016) to entangle the polarization in a stream of emitted photons. The spin-degree of freedom is useful for that purpose, thanks to its long coherence time, due to a weak interaction with the environment, yet with a great ease of direct control with optical pulses. This allowed Kroutvar et al. (2004) to implement optically fully-programmable spin memories. In two-dimensions, there is the prospect of taking advantage of exciton propagation, and thereby to implement more powerful functionalities. This, however, comes at the price of being more difficult to master and only proof-of-principle demonstrations of 2D excitonic devices, including some with similar functionalities as those above (light-source, memory storage, etc.), have been demonstrated. Transport applications start with the exciton conveyors, such as those implemented by Winbow et al. (2011) and Peng et al. (2022), that literally transport excitons on an electrostatic carpet powered by surface acoustic waves, whose amplitude and speed are directly controlled through the applied voltage and AC frequency, respectively. A near-field piezoelectric field periodically modulates the exciton energy to drag them over distances an order of magnitude greater than by diffusion alone, that is already very large. This could develop into a new kind of excito-phononic circuits. A technological grail is the transistor, whose electronic implementation comes with the drawback of high energy consumption and heat dissipation. Purely photonic transistors lack the nonlinearities inherent to the device. Excitons thus appear an ideal compromise to realize an opto-electronic transistor, also interfacing the two basic tenets of technology: electronics (control) and optics (communication). Excitonic transistors as well as their combination in a circuit, have been demonstrated by High et al. (2008) to effectuate such a conversion of photons into excitons that flow through the device before their ultimate reconversion into photons. The principle of an excitonic transistor is, similarly to its electronic FET model, to control via an applied voltage the flow of excitons through two terminals conditioned to the state of a third one. A transistor acting as a switch (as opposed to as an amplifier, the other typical function of a transistor) was demonstrated, with a control of the flux of excitons in the source electrode by a gate voltage. At the heart of the mechanism, an applied electric field creates an energy barrier or trap for IX and therefore can suppress or enable exciton diffusion. From the optical side, the exciton recombination rate can thus be controlled with an applied electromagnetic field. Three such excitonic transistors have also been coupled to share a common electrode, thereby realizing an excitonic circuit, with one application implemented to directionally switch the exciton flux. At this time, 2D excitonic transistors are not functional enough to power a substituting technology. The binding energies of the materials where they have been implemented require cryogenic cooling, and their performances do not yet compete with even decades-old electronics. While quantum devices would be worth running at cryogenic temperatures, classical devices should certainly operate at room temperature to rival those already existing, in which case strongly-bound excitons such as those provided by van der Waals structures are required. Emerging materials could, indeed, push forward excitons as strong contenders to replace electronics. These also reinforce the role of the excitons over the electrons and holes in conventional semiconductor devices, due to their strong binding, oscillator strengths and Coulomb interactions, so that new generations of excitonic LEDs, junctions, electrically controllable routers and transistors become possible, operating with currents as low as nanoamps. In the case of the transistor, room-temperature operation with a transport of excitons over five micrometers distance, has already been demonstrated by Unuchek et al. (2018). In addition to that, the rich valley-physics opens new functionalities, such as the control of light handedness that allowed Zhang et al. (2014b) to implement flexible chiral optoelectronics. These rapid developments open the route, not only toward an excitonic computer, but also entirely new types of devices such as transparent and stretchable screens.

Conclusion

Excitons have been part of condensed-matter physics since its early days and they remain at the forefront of its most active, fruitful and promising developments. They have retained throughout their history a mixed nature of being a compelling quasi-particle and a dubious one to truly or rigorously account for the complexity of condensed matter systems. In both cases, they are central, in one form or another, to a vast and varied range of phenomena. Even as they get tentatively discarded from even their excitonic resonances, they re-appear in the most unexpected places, such as metals. Excitons will likely remain unavoidable mental pictures, forever introduced as electron-hole pair bound states, and as technological applications—possibly room-temperature superconducting excitonic quantum devices—develop from ideas based on their conception, they will continue to occupy a central position in condensed-matter physics.

Abstract

This article elaborates on surface-enhanced Raman scattering (SERS) technique, increase of Raman scattering due to various factors namely; chemical effect, charge transfer, resonance, electromagnetic field amplification. The electromagnetic enhancement mechanism is caused by the electric field from the surface, surface plasmons excitation and surface electromagnetic waves. SERS technique increased the Raman intensity by factors up to 10^{15} using recent hybrid substrate materials such as graphene-based 2D and 3D nanostructures of silver and gold.

Key points

- The effects of electromagnetic (e.m.) amplification on Raman scattering.
- Electromagnetic enhancement for flat and rough surface, metal particles and clusters.
- Nanostructures in surface-enhanced Raman scattering.

Introduction

The subject of this article is the description of the properties of metal surfaces and metal particles that are sources of strong enhancement of the intensity of the scattered Raman light from molecules and thin films, which are in contact with them or in their close vicinity in the nanoscale range. First, the origin of the enhancement of the Raman intensity is discussed showing that the main source of the effect is the amplification of the electromagnetic (e.m.) field at the interface of two media (e.g., metal/dielectric), when surface e.m. waves and/or surface or localized plasmons are excited. The cases of flat and corrugated metal surfaces, single metal particles, and metal clusters are discussed. The last section is devoted to the illustration of the surface-enhanced Raman scattering (SERS), commonly characterized by enhancement of the Raman intensity of 4–8 orders of magnitude, and originated from metal (e.g., Au, Ag, Cu) surfaces which are rough on nanoscale (10–100 nm) and from metal nanoparticles and nanoclusters. Not all the subjects are treated in detail since some of them are presented exhaustively in other articles of this encyclopedia.

The origin of the enhancement of Raman intensities

As it is well known, Raman scattering is a nonlinear process (e.g., two photons and one quantum of vibration are involved) which is characterized by a very low cross-section, σ (in m^2), defined by the relation: $P_{SC} = \sigma I_{in}$, where P_{SC} is the power (in W) of the scattered light and I_{in} is the intensity of the exciting light (in Wm^{-2}). For the normal Raman scattering, the cross-section (average value $\approx 10^{-33} \text{ m}^2$) is nine orders of magnitude smaller than that of the infrared absorption process and this prevents the detection of a very small amount of material as it is necessary, for example, in surface science. To achieve the surface sensitivity (detection limit of a fraction of the monolayer), some enhancement in the process is necessary. Two mechanisms are possible sources of this

[☆]Change History: March 2022. S.N. Aqida updated abstract; add keypoints and summary, expanded text with additional review materials; updated list of reference; updated History.

enhancement. The first one is related to the cross-section itself. In some systems, molecules as well as crystals and films, at special frequencies σ present a resonant behavior due to the direct absorption of the incident photons by suitable electronic levels coupled with vibrational states. In this condition, that is, resonant Raman scattering, the intensity of the scattered light can be enhanced up to six orders of magnitude. In some cases, chemisorption on metal is accompanied by the formation of new electronic levels in the visible range for the adsorbate/metal system, allowing the resonant Raman scattering to occur. Of course, this resonant process (average enhancement factor 100), often indicated as “chemical effect,” is strongly dependent on the frequency of the exciting light and is specific to the excited system. The second source of Raman intensity amplification is related to the enhancement of the local electric field seen by the excited medium (e.g., adsorbed molecules on a metal surface or on a small metal particle). Indeed I_{in} being proportional to the square of the electric field amplitude of the excitation light, an increase of this amplitude by a factor 10^2 implies an enhancement of the Raman intensity by a factor 10^4 , for example. This enhancement mechanism of the Raman intensity, called “electromagnetic effect,” is somehow independent of the excited system and presents some specificity that allows one to discriminate it from the “chemical effect.” Of course, in some cases, both effects can contribute to the total Raman enhancement. The following sections illustrate the e.m. effect through the use of system models, namely various metal surfaces. Undoubtedly, the properties of the surface itself play an important role in the Raman enhancement. Among them, the surface shape and size, and also the frequency-dependent dielectric function of the metal, have to be considered.

Flat metal surface: Raman enhancement and surface selection rules

Consider the case of molecules adsorbed (or in the near proximity) on a flat metal mirror where an e.m. wave, impinging on with an angle of incidence θ , is reflected (Fig. 1) (Mattei, 2005).

The molecules see a local electric field at surface, E^{su} , that is due to the coherent superposition of the electric fields E^{i} and E^{r} of the incident and the reflected e.m. waves. Considering the two polarizations, s (TE) and p (TM), one has, for the x , y , and z components of the local field,

$$\begin{aligned} E_x^{\text{su}} &= E_{s,0}^{\text{i}}(1 + r_s) \\ E_y^{\text{su}} &= E_{p,0}^{\text{i}}(1 - r_p) \cos(\theta) \\ E_z^{\text{su}} &= E_{p,0}^{\text{i}}(1 + r_p) \sin(\theta) \end{aligned}$$

where $E_{s,0}^{\text{i}}$ and $E_{p,0}^{\text{i}}$ are the components of the incident electric field of s (TE) and p (TM) polarization, and r_s and r_p are the Fresnel coefficients, being:

$$\begin{aligned} r_s &= \left[\cos(\theta) - (\varepsilon - \sin^2(\theta))^{1/2} \right] / \left[\cos(\theta) + (\varepsilon - \sin^2(\theta))^{1/2} \right] \\ r_p &= \left[\varepsilon \cos(\theta) - (\varepsilon - \sin^2(\theta))^{1/2} \right] / \left[\varepsilon \cos(\theta) + (\varepsilon - \sin^2(\theta))^{1/2} \right] \end{aligned}$$

It is to be noted that the dielectric function $\varepsilon(\omega)$ is a complex function of the frequency ω (here the dependence on the wave vector of the light is neglected). In the case of metals, the real part $\text{Re}[\varepsilon(\omega)]$ can be strongly negative below the plasma frequency ω_p and almost zero around ω_p . It is easy to demonstrate that when $|\varepsilon|$ is very large, $r_s \rightarrow -1$ and $r_p \rightarrow +1$; it is just the opposite in the limit of very small $|\varepsilon|$, $r_s \rightarrow +1$ and $r_p \rightarrow -1$.

In the light scattering process, the local electric field $E^{\text{su}}(\omega_{\text{ex}})$ induces on the molecules at the surface a dipole moment μ , given by: $\mu(\omega_{\text{sc}}) = \alpha E^{\text{su}}(\omega_{\text{ex}})$, $\hat{\alpha}$, the polarizability of the molecules being a tensor of the second rank. The frequencies ω_{ex} and ω_{sc} are those of the incident and scattered light, respectively. $|\omega_{\text{ex}} - \omega_{\text{sc}}| = \omega_{\text{vibr}}$ is the frequency of the normal vibrational mode of the molecule involved in the scattering process. The scattered light, collected along a direction θ' far away from the surface, is then the superimposition of the light emitted directly in this direction together with the scattered light directed toward the metal surface

Fig. 1 Scheme of the Raman scattering of molecules (circles) adsorbed on the flat interface between a dielectric and a metal. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

and then reflected in the same direction (Fig. 1). Hence, the intensity of the scattered light, that is proportional to the square of the amplitude of the scattered electric field, will be affected by two surface contributions due to the reflection of the incident and of the scattered light as well. From the above expressions, the Raman intensities for the possible polarization (*s* and/or *p*) of the incident and scattered light can be obtained:

$$\begin{aligned}
 I_{ss} &\propto \omega_{sc}^4 |\alpha_{xx}(1+r_s)(1-r'_s)|^2 \\
 I_{ps} &\propto \omega_{sc}^4 |\alpha_{xy}(1-r_p)(1+r'_s) \cos(\theta) + \alpha_{zy}(1+r_p)(1+r'_s) \sin(\theta')|^2 \\
 I_{sp} &\propto \omega_{sc}^4 |\alpha_{yx}(1+r_s)(1-r'_p) \cos(\theta') + \alpha_{zx}(1+r_s)(1+r'_p) \sin(\theta')|^2 \\
 I_{pp} &\propto \omega_{sc}^4 |\alpha_{yy}(1-r_p) \cos(\theta) + \alpha_{yz}(1+r_p) \sin(\theta) [(1-r'_p) \cos(\theta') + [\alpha_{zy}(1-r_p) \cos(\theta) + \alpha_{zz}(1+r_p) \sin(\theta)] (1+r'_p) \sin(\theta')]|^2
 \end{aligned}$$

In these equations, all the quantities including the Raman polarizability components are referred to the frame of axis indicated in the figure with *z* along the metal surface normal. The primes indicate those quantities that are to be evaluated at the frequency and angle of the scattered light. It is clear that the observed scattered intensity depends in a quite complex way on the chosen scattering geometry (through the angles, the polarizations, and the Fresnel coefficients), the optical properties of the metal (through its frequency-dependent dielectric function), the symmetry of the molecular vibration, and the orientation of the molecule with respect to the surface (through the α_{ij} components of the polarizability). These relations determine the surface selection rules that control the Raman scattering of molecules adsorbed or posed on a flat metal surface. According to these selection rules, the Raman spectra can be very different from those of free molecules: the relative band intensities can be altered, some band can be strongly attenuated, others can be enhanced with respect to the free molecules. Even the dependence on the scattering frequency of the Raman intensity for single modes can deviate significantly from the ω^4 rule typical of the Raman scattering of free molecules. Finally, it is easy to verify that the maximum expected enhancement of the Raman intensity for any mode is 16 but for real systems, this value is seldom obtained, while enhancement values around 6–10 can be usually measured on flat metal mirrors.

Electromagnetic enhancement due to surface plasmons and surface electromagnetic waves: Flat and rough surfaces

As it is well known, at the vacuum/metal interface, surface collective charge modes, named surface plasmons (sp), polaritons do exist. They are evanescent waves produced by the oscillations of the surface charges, and propagate along the interface with a real wave vector *K*, given by

$$K = (\omega/c) \sqrt{\varepsilon_0 \varepsilon / (\varepsilon_0 + \varepsilon)}$$

In this equation, which represents the sp. dispersion curve (ω vs *K*), ε_0 and ε are the dielectric function of the dielectric (e.g., the air) and of the metal, respectively. No radiation is emitted from the surface in the two semispaces. The electric field that can be very intense at the surface, decays exponentially with the distance from the interface. Indeed, the components of the wave vector perpendicular to the surface are basically purely imaginary being: $K_{\perp} = i(\omega/c) |\varepsilon_1^2 / (\varepsilon_0 + \varepsilon)|^{1/2}$, where ε_1 is equal to ε_0 in the dielectric medium and to ε in the metal, respectively.

The sp. condition of existence and their dispersion curve are illustrated in Fig. 2, where for simplicity the metal dielectric function, ε , has been approximated with that of a free electron gas, namely: $\varepsilon = 1 - (\omega_p/\omega)^2$. In the figure, “reduced” adimensional quantities have been used for frequency, ω/ω_p , and surface wave vector, cK/ω_p .

It is clear from the comparison of the frequency dependences of the dielectric function and of the sp. dispersion that sp. do exist only for $\omega < \omega_p$, where the bulk modes cannot propagate in the metal, being $\varepsilon < 0$. For large *K* values, the sp. polaritons dispersion curve tends to frequency $\omega_p/(1 - \varepsilon_0)^{1/2}$ for which it is $\varepsilon = -\varepsilon_0$. Since the sp. are not radiative modes, they cannot be directly excited

Fig. 2 On the left, dielectric function vs reduced frequency, ω/ω_p , (ω_p is the plasma frequency) for a metal in the free electron gas approximation; on the right, surface plasmon polaritons (spp) dispersion curve for the metal/dielectric interface. *K* is the real wave vector parallel with the surface. The dashed straight line represents the photon dispersion in vacuum. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

by light propagating in one of the two media. Indeed, for a given frequency ω , the component parallel to the surface, $k_{\parallel}$ of the light wave vector will be always smaller than the corresponding component, K , of the sp. wave vector. As a matter of fact, it is always $k_{\parallel} = (\omega/c)\epsilon_0^{1/2} \sin \theta_i < (\omega/c)\epsilon_0^{1/2} < K$, where θ_i is the angle of incidence of the light on the metal surface.

Hence, the conditions for the energy and wave vector conservation cannot be simultaneously satisfied. Nevertheless, sp. excitation by light can be obtained in special conditions, namely: by grating coupling and in attenuated total reflection (ATR) geometry.

When a metal surface is sinusoidally modulated with a period d to form a grating, if the amplitude of the modulation is small compared with the wavelength of light, there is a modification of the light wave vector parallel to the surface, $k_{\parallel}$, into $K_n = (k_{\parallel} + 2\pi n/d)$ with $n = 0, \pm 1, \pm 2$, etc. It is then possible that, for suitable value of θ and n , the coupling condition, $K_n = K$, be satisfied, allowing the sp. excitation by light radiation (Fig. 3).

Wood anomalies in gratings, experimentally well known since the beginning of the twentieth century, can be attributed to this effect. Besides, sp. can have their wave vector modified by a surface modulation and become radiative waves. On this basis, it is clear that a rough metal surface can allow to some extent the excitation of sp. waves by light and their radiative emission.

Another way to excite sp. is the use of a prism in total reflection condition to generate surface e.m. evanescent waves that can couple with the spp. modes. The ATR in the so-called "Otto configuration" is illustrated in Fig. 4a, where a prism (dielectric constant ϵ_p) is separated by a thin layer of thickness d and dielectric constant $\epsilon_0 < \epsilon_p$ from a metal surface S . If a light beam strikes the interface prism/interlayer at an angle of incidence θ_i greater than the critical angle $\theta_c = \arcsin(\epsilon_0/\epsilon_p)^{1/2}$, total reflection occurs: no light is transmitted in the ϵ_0 medium. At the interface, an evanescent e.m. wave is produced with real wave vector parallel to the surface $k_{\parallel} = (\omega/c)\epsilon_p^{1/2} \sin \theta_i > (\omega/c)\epsilon_0^{1/2}$ and perpendicular wave vector component purely imaginary in

Fig. 3 Scheme of the spp. excitation of a metal grating of period d by incident light of wave vector K_i . $K_G = (2\pi n/d)$ is the surface wave vector due to the grating. $K_{\parallel}$ are the surface wave vectors parallel to the surface of the incident light and of the spp. excitations. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

Fig. 4 ATR geometries: (a) Otto configuration, (b) Kretschmann configuration: I, R and S represent the incident, the reflected, and the scattered beams, respectively; d is the thickness of the interlayer between prism and metal (a) or of the metal film (b). Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

the ϵ_0 media. The amplitude of the electric field decays rapidly in the interlayer, but, if the thickness d is of the order of the wavelength, the surface e.m. waves can interact with the sp. evanescent waves generated at the interface metal/interlayer when the wave vector ($k_{\parallel} = k$) and the frequency ($\omega_{\text{light}} = \omega_{\text{spp}}$) conservation laws are satisfied. When this resonant coupling occurs, the intensity of the reflected beam, R , is attenuated or “frustrated” allowing the detection of sp. modes.

Since both the Snell’s law (i.e., the conservation of the parallel component of the wave vector at the interface) and the dispersion relation of sp. are symmetrical with respect to ϵ_0 and ϵ , it is possible to interchange the role of these two media with respect to the prism. This is shown in Fig. 4b where the ATR in the so-called “Kretschmann configuration” is illustrated. The thickness d of the thin metal film must be sufficiently small to allow enough energy to reach the metal/dielectric interface. Again, attenuation of the intensity of the reflected light as a function of the frequency and of the angle of incidence allows the detection of sp. waves.

Calculated angular dependence of the reflectivity at 530 nm as a function of the angle of incidence in the Kretschmann configuration (prism ($\epsilon_p = 2.1$), metal film ($\epsilon = \epsilon' + i0.56$), air ($\epsilon_0 = 1$)) are presented in Fig. 5a for different values of d . The minimum of the reflectivity, corresponding to the excitation of the sp. at the interface metal/air, is deepest for an optimal film thickness. Note that the angle and the angular width of this minimum depend on the thickness, because in the case of thin film the sp. modes of the two interfaces fill each other, and influence and modify the corresponding dispersion curves depending on the distance d between the interfaces.

An important consequence of the excitation of the sp. waves by ATR is that the intensity of the electric field at the metal/dielectric (metal/air, in this case) interface can be significantly larger than that of the incident e.m. wave. As an example, in Fig. 5b, the field intensity enhancement, namely the ratio between the intensity of the electric field at the metal/air interface and the one of the incident wave at the prism/metal interface, is reported as a function of the angle of incidence, for the case of Fig. 5a. As it is clear, in the optimal condition, an enhancement of two orders of magnitude can be achieved. As a consequence, enhanced Raman scattering from molecules adsorbed on the metal/air interface can be excited in this configuration. Considering that the scattered light can be also converted in sp. excitations and, through the ATR system, into light emitted in the prism at a suitable angle, a final enhancement of about four orders of magnitude can be obtained. Indeed, in the literature, several experimental evidences of enhanced Raman scattering using ATR configuration, with the enhancement factor ranging from a few tens to ten thousand, have been reported. For example, studies by enhanced Raman spectroscopy of metal/liquid interfaces and Langmuir–Blodgett layers on smooth Ag surfaces have been reported. Using Langmuir–Blodgett technique, modifying sizes and shapes of nanoparticles shapes into nanostars, nanorods and nanospheres produced optimal performance that tuning plasmonic coupling (Tahghighi et al., 2020; Tim et al., 2022).

Besides, a combination of ATR spp. excitation and near-field Raman spectroscopy has been used to scan, with high sensitivity, the species present on the electrode surfaces.

Finally, for completeness, it is important to note that the conversion of traveling e.m. waves into surface evanescent e.m. waves can be used to enhance Raman scattering intensity at the interface between two dielectric media, when the exciting light strikes the interface from the denser medium in total reflection condition. As a matter of fact, the Raman scattering excited in a total reflection condition has been used for studying adsorbates, films, and even the surface phonon-polaritons dispersion at the interface between a prism and a transparent crystal.

Fig. 5 ATR in the Kretschmann configuration, wavelength 530 nm. (a) Angular dependence of the reflectivity in the prism for various Ag film thicknesses. (b) Angular dependence of the electric field intensity at the air/metal interface for various Ag film thicknesses. Reproduced from Mattei G. Electromagnetic enhancement due to metal particles

The following case is considered first, that is, the case of single isolated metal sphere of radius R , small with respect to the light wavelength λ : that is, $R \ll \lambda$ ("Rayleigh limit" or "electrostatic approximation"). If such a sphere, of dielectric function $\varepsilon(\omega)$ and embedded in a medium of dielectric function ε_0 , is irradiated by an e.m. wave with electric field amplitude E_i polarized in the z direction (see scheme in Fig. 6), a dipole moment $p = gR^3E_i$ is generated inside the sphere. The potential, V , outside the sphere, due to the incident electric field and the electric dipole p , expressed in spherical coordinates (r, θ, φ) , is

$$V(r, \theta) = E_i(r - gR^3/r^2) \cos(\theta)$$

where $g = (\varepsilon - \varepsilon_0)/(\varepsilon + 2\varepsilon_0)$. The radial, E_r , and tangential, E_t , components of the electric field at the surface of the sphere can be obtained in a standard way from the potential. The intensity of the two electric components, averaged over all the solid angle, are proportional to

$$\begin{aligned} \bar{E}_r^2 &\propto |1 + 2g|^2 \\ \bar{E}_t^2 &\propto 2|1 - g|^2 \end{aligned}$$

Because of the resonant denominator in g , when it is $\text{Re}[\varepsilon(\omega)] = -2\varepsilon_0$ (condition of excitation of localized sp. of the metal sphere) and the $\text{Im}[\varepsilon(\omega)]$ is small (as in the case of coinage metals), the electric field intensity at the surface of the metal particle can be much larger than that of the incoming radiation.

Let the light scattering process be considered now, assuming that the molecules are adsorbed on the spherical metal particle with the z -axis of the molecule-fixed coordinate frame along the normal to the surface. The average Raman intensity can be simply considered as dependent on the average intensity of the incident and scattered fields. The metal particle enhances not only the incident electric field on the molecule, but also the Raman scattered field. It acts as an antenna, through the dipole induced in it by the molecular dipole, which amplifies the scattered light intensity. Considering the polarizability tensor of the molecule, three kinds of vibrations can be distinguished. The α_{zz} -type modes require a radial field, E_r , to be excited and produce an induced dipole with only a radial component. Hence, the average intensity due to only the radial electric field will contribute twice to the detected Raman intensity: once in excitation and once again in emission. Similar considerations can be made for the other two kinds of modes, $\alpha_{xx}, \alpha_{yy}, \alpha_{xy}$ (only tangential components), and α_{xz}, α_{yz} (mixture of tangential and radial components).

The intensity of enhanced Raman spectra of these kinds of modes will therefore depend on the frequency through the following functions:

$$\begin{aligned} &\alpha_{zz} \text{ -type} \\ &\bar{E}_n^2 \bar{E}_n'^2 \propto |1 + 2g|^2 |1 + 2g'|^2 \\ &\alpha_{zz}, \alpha_{yy}, \alpha_{xy} \text{ -type} \\ &\bar{E}_n^2 \bar{E}_n'^2 \propto |1 - g|^2 |1 - g'|^2 \\ &\alpha_{xy}, \alpha_{yz} \text{ -type} \\ &\frac{1}{2} (\bar{E}_n^2 \bar{E}_t'^2 + \bar{E}_t^2 \bar{E}_n'^2) \\ &\propto [|1 + 2g|^2 |1 - g'|^2 + |1 - g|^2 |1 + 2g'|^2] \end{aligned}$$

where the prime indicates quantities to be evaluated at the frequency of the scattered light. In Fig. 7 the dependence on the frequency of these functions is presented for a fictitious free-electron metal particle. For simplicity, it has been considered that ε_0 and $g = g'$.

Fig. 6 Scheme of the Raman scattering from a molecule adsorbed on a metal spherical particle of radius R . E_i and E indicate the electric field of the incident and of the scattered light, respectively; p_m and p are the electric dipole induced in the molecule and in the metal particle, respectively. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

Fig. 7 Wavelength dependence of the enhancement factors for the three kinds of molecular modes for a molecule adsorbed on a metal particle of radius R in the Rayleigh limit (R' wavelength of the exciting light). Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

As expected, all three functions have a sharp maximum (corresponding enhancement factor 10^6) at a wavelength for which $\text{Re}[\varepsilon(\omega)] = -2$. Besides, at longer wavelengths, the α_{zz} -type modes dominate in the Raman spectrum, whereas at lower wavelengths all the modes are almost equally enhanced. It is clear that the number and the relative intensity of the bands present in the enhanced Raman spectrum can vary significantly with the frequency of the excitation light. Indeed, often very rich spectra can be measured with the distribution of the intensity that apparently violates the surface selection rules.

The model discussed above, although quite simple, provides the main features associated with the enhanced Raman scattering of molecule adsorbates on small metal particles. A more realistic model must include the effects of the particle shape and size distribution.

As the particle size increases beyond the Rayleigh regime, the used electrostatic approximation is not longer valid. The computer-intensive Lorenz-Mie or electrodynamics formalism, which accurately accounts for the effects due to the phase retardation and the quadrupole and higher order poles, must be used to obtain an exact solution. Also the conversion of the near-field electric field due to the molecule through the metal particle acting as an antenna into far-field radiation must be then taken into account. Generally, as a consequence, the intensity enhancement of the Raman scattered radiation can be significantly reduced.

Considering the shape effect, in the case of an isolated spheroid of eccentricity b/a (a and b being the length of the short and the long principal axis, respectively), in presence of an external electric field (due to an e.m. wave) oriented along the b -axis, it can be demonstrated that the Raman enhancement is always larger for the more aspherical particles. In the limiting case of $(b/a) \rightarrow \infty$, the calculated enhancement at the tip positions can be of some order of magnitude larger than for the case of spherical particles ("lightning rod effect").

Finally, to treat the case of interacting metal particles and of metal clusters that are also of great practical relevance, various model systems have been considered, for example, two interacting metal spherical particles ("bispheres"), aggregates of metal spheres, set of parallel metal cylinders of variable diameter and interdistance, etc. The calculation of the optical properties of these systems and of the effects on the Raman scattering is generally quite complex and can include retardation effects and high-order multipoles. The general result is that the interaction between two plasmon-resonant nanoparticles leads to additional resonances (at longer wavelengths) for the coupled system. Besides, the electric field in the gap between the particles or around the contact region (for two contacting particles) can be much strong in other places near the particles and stronger than in any place around an isolated particle. Hence, the Raman enhancement can be much larger than for isolated metal nanoparticles. Indeed, enhancement value as large as 10^8 – 10^9 has been predicted for such metal systems.

It has been recognized early that small-particle composites, or disordered clusters present in metal colloidal solution, as well as some rough metal surface have a fractal character. Studies have been developed to relate the enhancement of the local electric fields in these systems with their fractal dimension. An interesting example is illustrated in Fig. 8, where the calculated dependence on the wavelength, λ , of the local electric field enhancement factor for three systems made by 500 metal spherical nanoparticles ($d''\lambda$) is presented.

In the case of a gas of spherical particles (RGP curve), the characteristic sharp feature due to the excitation of the sp. in isolated spheres is clearly observed below 400 nm. The absence of other features above that wavelength indicates a very little interaction among the particles. For the ordered particle aggregate (CPSP curve), the single-particle excitation is attenuated and the enhancement increases in the long-wavelength region of the spectrum as a result of the mutual particle interactions. Clearly, the largest enhancement in the local field, up to 10^3 times the one of isolated particle, is predicted for the fractal system (CCA curve). On this basis, huge enhancement factors for the intensity of Raman scattering from molecules on fractal systems can be expected.

Fig. 8 Wavelength dependence of the averaged local field intensity for a gas of spherical particles (RGP), a close-packed crystal of spherical particles (CPSP), and a fractal aggregate (CCA). Surface-enhanced Raman scattering

SERS was discovered, although not recognized as such, by M Fleishman and co-workers in 1974. They observed an intense Raman signal from pyridine adsorbed onto a roughened silver electrode surface from an aqueous solution. They attributed, erroneously, the observed enhancement of the Raman signal to an increase of the surface area due to the roughening process. In 1977, the nature of this enhancement was attributed by D L Jeanmaier and R V Van Duyne, and independently by M G Albert and J A Creighton to a new phenomenon related with the increase of the effective Raman cross section of adsorbates on some rough metal surfaces. Since then, many studies and works have been carried out to understand the fundamental aspects as well as to exploit all the applicative potentialities related with SERS. A wide variety of metal substrates have been found to exhibit SERS: electrochemically roughened electrodes, chemically etched surfaces, colloids (especially aggregated colloids), island films, particles grafted on silanized glasses, regular particle arrays, hybrid, etc. The dominant metals in SERS are the coinage (Cu, Au, Ag) and alkali (Li, Na, K) metals. Moreover, although with lower enhancement, transition metals (e.g., Pt, Ru, Rh, Pd, Fe, Co, Ni and their alloys) have also been used. Generally, the observed enhancement ranges from 10^4 up to 10^8 in standard SERS measurements. The largest enhancement occurs for surfaces which are rough on the nanoscale (10–100 nm).

Advances in nanofabrication transpired different types of SERS substrates, such as Ag nanospheres, nanorods and nanostars (López-Lorente, 2021; Tahghighi et al., 2020), hexagonal nanopatterns (Chakraborty et al., 2021), dimple nanostructures/nano-bowls (Li et al., 2021; Yang et al., 2022), 3D hybrids nanostructures (Mehrvan et al., 2017), (Geng et al., 2021) that produced high-density hot spots, leading to a strong Raman signal. Specifically in solar cells panel application, hybrid nanostructures substrate resulted in ultra-high electromagnetic field enhancement where Ag nanoparticles decorated silicon double nanocones (Si-DNCs) array could produce 22 times stronger SERS signal than crystalline Si (Mehrvan et al., 2017). This is also achievable in the deposition of Ag nanoparticles on Au-coated surface textured monocrystalline Si solar cell substrates. Thicker Au coating on textured Si increases Raman intensity between 1400 and 1800 cm^{-1} wavenumber due to the chemical enhancement of Rhodamine 6G (R6g) molecular charge transfer, as shown in Fig. 9 (Li et al., 2020).

In Lofrumento et al. (2015), for molecules adsorbed on the surface of a metal nanoparticle, the Raman signal can be enhanced by factors as high as 10^{15} caused by combined effects of strong local field and direct chemical interactions.

Composite SERS substrate combines graphene-based with noble metallic nanostructure (nanoparticles, nanoshells, nanowires, nanodots and nanoporous films) (Zhao et al., 2015; Li et al., 2015; Ding et al., 2015).

Graphene oxide (GO) has excellent electronics and structural properties and has been used as a substrate for enhancing Raman scattering of adsorbed analyte molecules. GO-based SERS decorated with noble metallic nanoparticles allow combination of electromagnetic mechanism and chemical mechanism effects (Li et al., 2015).

Enhanced SERS activities are also found in GO nanosheet-silver nanoparticles composites and gold nanoparticles on graphene sheets hybrids (Ding et al., 2015; Lee et al., 2014). Furthermore, developing 3D hybrid substrates has created more hot spots in nanoparticle–nanoparticle junctions which can be comprised of different sizes and geometry such as nanosphere and nanooctahedra. (Kaushik et al., 2022). Dimple nanostructures enhanced the absorption of incident light and generated multiple hotspots that occurred in nano-tips gaps (at the top of the structure) of less than 10 nm which significantly amplify Raman signals (Li et al., 2021; Yang et al., 2022).

Fig. 9 SERS spectrum of R6G on the (50 nm and 100 nm) gold-coated flat bulk silicon and surface textured monocrystalline silicon solar cell substrates. Reprinted from Li R., Lei J., Zhou Y., Li H. Hybrid 3D SERS substrate for Raman spectroscopy. *Chemical Physics Letters* 754: 137733, Copyright (2020), with permission from Elsevier.

Semiconductors such as TiO_2 and ZnO have been used as SERS-active substrates, (reviewed by Zhao et al., 2015). In fact, TiN nanorods can produce electromagnetic field enhancements similar to those of gold nanostructure (Zhao et al., 2015).

The main observed features of SERS spectra are the followings: (1) the intensities of the bands generally fall off with increasing vibrational frequency (e.g., C-H stretching vibrations are relatively weak, overtones and combination bands are seldom observed), (2) selection rules are relaxed, even forbidden Raman modes can be detected, (3) the spectra tend to be completely depolarized, (4) excitation profiles differ from the dependence on the fourth power of the frequency, ω_{in}^4 , typical of nonresonant Raman scattering, and (5) although the enhancement is mainly concentrated on the first layer of adsorbates, often the effect can extend to a quite long range (up to tens of nanometers).

As suggested before, two mechanisms must be considered to explain SERS, namely the e.m. and the chemical effects. Previous sections describe the foundation of the e.m. effect of the SERS, since the behavior and the properties of metal substrates and particles that sustain the SERS effect can be described using the models presented there. First of all, the dominance of the coinage metals arises from the optical properties of these metals as indicated for Ag in Fig. 10.

Indeed, the resonance condition with the sp. (e.g., $\text{Re}[\varepsilon(\omega)] = -2\varepsilon_0$) is satisfied at visible frequency generally used for Raman spectroscopy. Besides, the imaginary part of the dielectric function, $\text{Im}[\varepsilon(\omega)]$, which is related with losses in the material, is very small at the resonance frequency, thus allowing strong enhancement of the local electric field on the rough surface and colloidal particle made with these metals.

The e.m. model explains many of the experimental features of SERS listed above, including the order of magnitude of the observed enhancement of the Raman intensities. For example, in feature (1), the need to have simultaneously the frequency of the incident and of the scattered light as close as possible to the resonance frequency implies a more effective enhancement for the vibrations with lower Raman shift. The modification of the Raman selection rules as well as the deviation from the ω_{in}^4 dependence of the Raman intensity for SERS are also suggested from the model. The dipole decay law with the distance explains the long-range effect of the SERS enhancement often observed. Finally, the observed depolarization can be easily explained considering that a SERS-active surface is a collection of roughness features of different sizes and shapes into which the molecules adsorb in a variety of orientations and the occurrence of multiple scattering.

Although the e.m. model is able to explain most of the experimental SERS features, some observations strongly support the existence of a second mechanism of Raman enhancement of adsorbates on metal, namely the “chemical effect.” Synonyms found in literature for chemical effect in SERS are charge-transfer excitations, short-range effects, atomic-scale roughness, SERS-active sites, adatoms, and energy-transfer excitations. Some SERS measurements indicate a dependence of the observed signal on the special studied adsorbates that cannot be explained by an e.m. effect. For example, the SERS spectra of CO and N_2 molecules that exhibit near identical polarizability differ from a factor 200, hard to explain invoking only the e.m. enhancement. A second evidence supporting the chemical effect is the potential dependence of SERS measured in electrochemical experiments. When the potential is scanned at a fixed laser frequency, or the laser frequency is scanned at a fixed potential, broad resonances are observed.

A simple Raman resonance mechanism can provide the explanation of this chemical effect. It is not unusual that the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the adsorbate, which arise from the chemisorption, are symmetrically positioned in energy with respect to the Fermi level of the metal, as indicated in Fig. 11.

Since for molecules normally studied by SERS the LUMO is typically in the ultraviolet, the charge transfer excitations (either from the metal to the molecule or vice versa) can occur at about half the energy of the intrinsic intramolecular excitations, namely in the visible region of the spectrum.

Fig. 10 Experimental dielectric function, $\varepsilon(\omega)$, of a silver film. The combined contributions of the free electron and interband transitions cause $\text{Re}[\varepsilon(\omega)]$ of Ag to approach 0 in the visible range even though the free electron plasma frequency is in the ultraviolet. In the same range $\text{Im}[\varepsilon(\omega)]$ is quite small. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. Fig. 11 Typical energy level diagram for a molecule adsorbed on a metal surface. Possible charge transfer excitations are shown. Reproduced from Mattei G. (2005) Optical properties of surface layers enhanced Raman scattering. In: Bassani F., Liedl G.L., Wyder P. (eds.) *Encyclopedia of Condensed Matter Physics*. Elsevier.

In recent years, the advent of new very sensitive Raman instrumentation with high spatial resolution, for example, micro-Raman and near-field systems, allowed the selective observation of single particles by SERS. Those experiments demonstrated that SERS from adsorbed species on metal particles show huge enhancement, around 10^{12} – 10^{15} , allowing the detection of the Raman signal from a single molecule and opening new fields of applications. Theoretically, the Raman signal of molecule can be enhanced up to a 10^{13} factor for a potential single molecule detection (Giovannozzi et al., 2014). In the case of experiments performed on aggregate clusters of colloidal particles, their fractal nature has been invoked to explain the observed enhancement whereas in the case of single particles (in the dimension range of 100–500 nm), the multiplicative effect of resonance Raman enhancement of the molecule and surface enhancement at the metal surface has been considered the main source of the effect. Besides, not all the particles showed an efficient enhancement but only a few called “hot spots” did so. In most cases there is a time dependence

of the intensity of every Raman band, which is called “blinking.” Finally, this huge Raman enhancement can be reconciled with the more commonly observed value (10^6 – 10^8) for SERS considering the particles population averaging that occurs in conventional experiments (macro-Raman). These last findings have attracted considerable attention from both basic and practical viewpoints. Indeed, a detailed understanding of the mechanisms operating to generate such a huge local Raman enhancement is not achieved yet and, hence, represents a very interesting area for study. Potential applications are, for example, in analytical chemistry as an ultrasensitive detection technique and in the development of micro-instrumentation, by combining scanning near-field microscopy with SERS.

Conclusion

The factors for Raman scattering enhancement are described. The amplification of electromagnetic field was discussed on flat and roughed surface, metal particles, and metal clusters. In SERS technique, electromagnetic and chemical effect have been discussed involving dominant metals (gold, silver and copper), alkali and transition metals at nanoscale surface conditions. Recent researches have developed significant hybrid substrate, and 3D nanostructures to amplify Raman signals for specific applications.

Introduction

Photonic crystals are materials whose dielectric function is periodic in one, two, or three spatial dimensions (1D, 2D, 3D). The propagation properties of photons in periodic media are analogous to those of electrons in crystalline solids, as covered by several sections of the encyclopedia. Translational invariance leads to the validity of the Bloch theorem (called Floquet theorem in optics) and to the formation of allowed and forbidden frequency regions. The allowed states of the electromagnetic field are organized into “photonic bands,” in analogy to electron bands in periodic solids. A frequency window for which light cannot propagate is named a “photonic gap” and periodic dielectric media are often called “photonic bandgap materials.”

The concept of a 1D periodic dielectric medium has been a familiar one in optics, where it is known as a distributed Bragg reflector (or dielectric mirror) with well-defined stop bands. However, a stop band (or photonic gap) in 1D forbids propagation of light only in a limited angular cone. The field of photonic crystals is considered to have started in 1987 with seminal papers dealing with the control of spontaneous emission and with light localization in three dimensions. Indeed, the presence of a full photonic bandgap in 3D leads to the suppression of vacuum fluctuations of the electromagnetic field and, therefore, to the inhibition of spontaneous emission of a light source at frequencies within the bandgap. Moreover, the presence of disorder may lead to a weak localization of light at frequencies close to a band edge. Photonic crystals are now of great interest for basic physical properties related to the control of light propagation, radiation–matter interaction and quantum electrodynamic effects, localization and microcavities, nonlinear properties as well as for applications to optoelectronic and photonic devices such as lasers, optical fibers, filters, dispersion compensators, and integrated optical interconnects.

The article starts with the general properties of the photonic band structure and discusses the main theoretical approaches for calculating photonic bands and optical properties. Then photonic bands in three and two dimensions as well as photonic crystals embedded in planar waveguides (also known as photonic crystal slabs) are described. Defect states in photonic crystals are then considered. This section concludes with a few remarks about methods for measuring the photonic band dispersion.

Photonic Band Structure: General Properties

Maxwell equations for the electromagnetic field in matter with neither free charges nor currents can be cast into a second-order equation for the harmonic components of the electric field

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) = \left(\frac{\omega^2}{c^2} \right) \varepsilon(\mathbf{r}) \mathbf{E}(\mathbf{r}) \quad [1]$$

or of the magnetic field

$$\nabla \times \left[\frac{1}{\varepsilon(\mathbf{r})} \nabla \times \mathbf{H}(\mathbf{r}) \right] = \frac{\omega^2}{c^2} \mathbf{H}(\mathbf{r}) \quad [2]$$

Here, nonmagnetic media ($\mu(\mathbf{r}) = 1$) are assumed. The first equation should be combined with the divergence equation $\nabla \cdot \varepsilon(\mathbf{r}) \mathbf{E}(\mathbf{r}) = 0$, while the second one requires $\nabla \cdot \mathbf{H}(\mathbf{r}) = 0$. The equation for the magnetic field is normally taken as the starting point for photonic band structure computations for two reasons. First, it has the form of an eigenvalue problem $\Theta \mathbf{H}(\mathbf{r}) = (\omega^2/c^2) \mathbf{H}(\mathbf{r})$, with Θ being a Hermitian operator. Second, the divergence equation for the magnetic field does not contain the dielectric function and is easier to implement. Working with a Hermitian eigenvalue problem is convenient from a computational point of view and has strong analogies with the matrix formulation of quantum mechanics.

The basic electromagnetic equations have a very useful property of “scale invariance.” If $H(\mathbf{r})$ is a solution at frequency ω corresponding to the dielectric constant $\varepsilon(\mathbf{r})$, then the scaled system with dielectric constant $\varepsilon'(\mathbf{r}) = \varepsilon(\mathbf{r}/s)$ has a solution $H'(\mathbf{r}) = H(\mathbf{r}/s)$ with frequency $\omega' = s\omega$. Reducing the length scale of the system by a factor s leads to eigenfrequencies that are multiplied by the same factor. Thus, there is no fundamental length scale for the photonic problem (unlike for electrons in solids, for which the Bohr radius is the natural unit of length).

A periodic dielectric medium (in 3D, say) is invariant under translations by vectors $\mathbf{R} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3$ ($n_1, n_2, n_3 \in \mathbb{Z}$), where $\mathbf{a}_1, \mathbf{a}_2$, and $\mathbf{a}_3$ are primitive vectors and the set of all $\mathbf{R}$'s forms a “Bravais lattice.” The dielectric constant satisfies the relation

$$\varepsilon(\mathbf{r} + \mathbf{R}) = \varepsilon(\mathbf{r}) \quad [3]$$

and the magnetic field has the form implied by the Bloch–Floquet theorem:

$$H_{nk}(\mathbf{r} + \mathbf{R}) = e^{ik \cdot \mathbf{R}} H_{nk}(\mathbf{r}) \quad [4]$$

where $\mathbf{k}$ is the Bloch vector (which may be restricted to the first Brillouin zone or Wigner–Seitz cell of the reciprocal lattice) and n is a discrete band index. The frequency eigenvalues have the form $\omega = \omega_n(\mathbf{k})$ and the set of all frequencies for $\mathbf{k}$ spanning the first Brillouin zone is called a photonic band. In addition to translational invariance leading to Bloch vector conservation, discrete rotational symmetries of the lattice may also be used to analyze the photonic bands, again in close similarity to the electronic problem. The density of states (DOS) is defined as

$$N(\omega) = \sum_n \int_{\text{BZ}} \delta(\omega - \omega_n(\mathbf{k})) d^3\mathbf{k} \quad [5]$$

and is strongly modified as compared to the photonic DOS in vacuum or in a homogeneous medium, which increases with the square of the frequency.

Theoretical Methods

The most common method for calculating photonic band structures consists of expanding the magnetic field on a basis of plane waves that satisfy the Bloch theorem and the divergence equation:

$$H_{nk}(\mathbf{r}) = \sum_{\mathbf{G}, \lambda} c_n(\mathbf{k} + \mathbf{G}, \lambda) \hat{\mathbf{e}}(\mathbf{k} + \mathbf{G}, \lambda) e^{i(\mathbf{k} + \mathbf{G}) \cdot \mathbf{r}} \quad [6]$$

where $\mathbf{G}$ are reciprocal lattice vectors and $\hat{\mathbf{e}}(\mathbf{k} + \mathbf{G}, \lambda)$, $\lambda = 1, 2$ are unit and mutually orthogonal polarization vectors perpendicular to $\mathbf{k} + \mathbf{G}$. The second-order eqn [2] is transformed into the matrix equation

$$\sum_{\mathbf{G}', \lambda'} H_{G\lambda, G'\lambda'} c_n(\mathbf{k} + \mathbf{G}', \lambda') = \frac{\omega^2}{c^2} c_n(\mathbf{k} + \mathbf{G}, \lambda) \quad [7]$$

where

$$H_{G\lambda, G'\lambda'} = |\mathbf{k} + \mathbf{G}| |\mathbf{k} + \mathbf{G}'| \times \varepsilon^{-1}(\mathbf{G}, \mathbf{G}') \begin{bmatrix} \hat{\mathbf{e}}_2 \cdot \hat{\mathbf{e}}_2' & -\hat{\mathbf{e}}_2 \cdot \hat{\mathbf{e}}_1' \\ -\hat{\mathbf{e}}_1 \cdot \hat{\mathbf{e}}_2' & \hat{\mathbf{e}}_1 \cdot \hat{\mathbf{e}}_1' \end{bmatrix} \quad [8]$$

and $\varepsilon^{-1}(\mathbf{G}, \mathbf{G}') \equiv \varepsilon^{-1}(\mathbf{G} - \mathbf{G}')$ is the Fourier transform of $\varepsilon^{-1}(\mathbf{r})$. Numerically, the linear eigenvalue problem is solved by retaining a finite number of reciprocal lattice vectors and using standard matrix diagonalization routines or more efficient methods based on fast Fourier transforms and iterative eigensolvers. The accuracy of the method depends on the number of plane waves in the basis and on their ability to reproduce the spatial variations of the magnetic field in the periodic structure and Maxwell boundary conditions when dielectric discontinuities are present. It turns out that convergence of the method is substantially improved when $\varepsilon^{-1}(\mathbf{G}, \mathbf{G}')$ is obtained by first calculating $\varepsilon(\mathbf{G}, \mathbf{G}') \equiv \varepsilon(\mathbf{G} - \mathbf{G}')$ as the Fourier transform of $\varepsilon(\mathbf{r})$ and inverting the resulting matrix numerically. Still, convergence of the method should always be checked and it may become problematic in special situations (e.g., high dielectric discontinuities and/or complex bases in the unit cell with close-packing dielectric spheres).

Just like plane-wave expansion, other techniques for photonic band structure calculations are borrowed from corresponding methods for the electronic problem. For example, in the case of spherical (for 3D) or circular bases (for 2D), the Korringa–Kohn–Rostoker method based on expanding the Green function in the basis of symmetry-adapted functions satisfying appropriate boundary conditions can be applied. This method has the advantage that it can easily incorporate frequency dispersion of the dielectric function (thus it can be used, for example, for photonic crystals containing metallic components), but it can be applied easily only to structures with bases of special symmetry.

The calculation of photonic bands assumes ideal structures, that is, infinitely extended in space and without imperfections. On the other hand, real samples are always finite and carry a certain degree of imperfection. Furthermore, there are quantities such as the transmission and reflection coefficients that manifest the existence of photonic bandgaps and are relatively easy to obtain

experimentally. Among the numerical methods that are able to compute transmission and reflection, the most widely used are the transfer matrix, the scattering matrix, and the finite-difference time-domain method.

The transfer matrix method works in real space. The Maxwell curl equations are discretized on a mesh of subcells, so that the field propagation in the structure is defined by a nearest-neighbor interaction. The matrix of the resulting linear system of equations is called a “transfer matrix,” as it transfers the fields from a subcell to another. Since the interaction is limited to the first neighbors, the matrix is sparse. Propagation across the whole structure is obtained by multiplication of sparse matrices. Once the transfer matrix is obtained, the calculation of transmission and reflection is straightforward. It is worth mentioning that when the system is periodic, the eigenvalues of the transfer matrix of a single unit cell yield an alternative method for computing the photonic band structure. This is especially useful when dealing with dispersive media.

The scattering matrix method is more suitable for the study of photonic crystal slabs (see description below). It computes reflection, transmission, and diffraction coefficients for propagation along a direction perpendicular or parallel to the waveguide plane. Maxwell equations are first solved in each layer by plane wave expansion. Then, using the scattering matrix (S), instead of the transfer matrix, boundary conditions are imposed at each interface. The S -matrix connects the ingoing amplitudes to the outgoing amplitudes. The scattering matrix $S(0, N)$ of the whole structure is constructed starting from the scattering matrix of the first interface $S(0, 1)$, by applying the recursion formula $S(0, l) \rightarrow S(0, l+1)$. The S -matrix yields better numerical stability than the transfer matrix.

When working with more complex systems, with imperfections or explicitly designed defects, a more flexible numerical approach is required. This is fulfilled by the finite-difference time-domain (FDTD) method. The derivatives in the Maxwell curl equations

$$\nabla \times E = -\frac{1}{c} \frac{\partial B}{\partial t}, \quad \nabla \times H = +\frac{1}{c} \varepsilon(r) \frac{\partial E}{\partial t} \quad [9]$$

are discretized by central finite differences, both in space and time. The electromagnetic field is thus defined on two meshes in space and time, one for the E field and one for the H field. These meshes are interlaced in order to have each E field position surrounded by nearest neighbor H field positions and vice versa. The equations are recast in the so-called “Yee algorithm,” which is illustrated here for a two-dimensional case:

$$E_x|_{i,j+1/2}^{n+1/2} = E_x|_{i,j+1/2}^{n-1/2} + \frac{c\Delta t}{\varepsilon_{i,j+1/2}} \left(H_z|_{i,j+1}^n - H_z|_{i,j}^n \right) \quad [10]$$

$$E_y|_{i+1/2,j}^{n+1/2} = E_y|_{i+1/2,j}^{n-1/2} - \frac{c\Delta t}{\varepsilon_{i+1/2,j}} \left(H_z|_{i+1,j}^n - H_z|_{i,j}^n \right) \quad [11]$$

$$H_z|_{i,j}^{n+1} = H_z|_{i,j}^n - \frac{c\Delta t}{\Delta x} \left(E_y|_{i+1/2,j}^{n+1/2} - E_y|_{i-1/2,j}^{n+1/2} \right) + \frac{c\Delta t}{\Delta y} \left(E_x|_{i,j+1/2}^{n+1/2} - E_x|_{i,j-1/2}^{n+1/2} \right) \quad [12]$$

Looping on i, j (space), and n (time) simulates the propagation of the electromagnetic field through the structure. Once the Yee algorithm has been implemented, the discretization of the dielectric constant $\varepsilon(r)$ is the only step that needs to be adapted to the specific simulation. This is a great advantage of FDTD with respect to the transfer matrix method. A Gaussian pulse is sent along a chosen direction, while detection lines collect the incident and outgoing power. The transmission coefficient is simply the ratio of outgoing to incident power. The reflection coefficient can be obtained in a similar manner. When the system is periodic, it is also possible to obtain the band structure from an FDTD simulation. Specific implementations of the FDTD method have been developed to treat media with strong frequency dispersion, such as metallic or metallo-dielectric systems.

Three-Dimensional Photonic Crystals

The first photonic structure that has been shown to possess a complete bandgap in three dimensions is the diamond lattice of dielectric spheres in air or air spheres in a dielectric material. The photonic gap opens provided the dielectric constant is large enough and it exists in a wide range of filling factors. Another simple 3D structure with a complete bandgap is the f.c.c. lattice of air spheres in a dielectric material: this is often called the “inverse opal” structure. An example of photonic bands and DOS for this structure is shown in Figure 1. The frequencies are given in dimensionless units $\omega a / (2\pi c) \equiv a/\lambda$, where a is the lattice constant, and as such they are invariant under a scale transformation. A full bandgap forms between the eighth and ninth bands with a relative width $\Delta\omega_g/\omega_g \approx 4\%$. On the other hand, no gap is formed between lower-lying bands, but a pseudogap with low photonic DOS occurs around $a/\lambda = 0.52$: a degeneracy between the second and the third bands at the W point and along the XU line prevents a gap from opening.

The inverse opal is derived from the (direct) opal structure, that is, an f.c.c. lattice of dielectric spheres in air: indeed, the opal is a natural gem consisting of a close-packed lattice of silica spheres with an f.c.c. arrangement. Artificial opals can be obtained by self-assembling of spheres in a colloidal solution. The voids are then filled with a high-index material (Si or TiO_2) and the template is subsequently removed to obtain the inverse structure. This procedure allows one, in principle, to realize a photonic crystal with a complete bandgap in the optical region. In real systems, however, a small amount of disorder is always present: the gap shown in Figure 1 is not very robust as it is relatively narrow and is formed between higher-lying bands, which are very sensitive to disorder.

Figure 1 (a) Photonic bands and (b) DOS for an f.c.c. structure of close-packing air spheres in a dielectric material with $\varepsilon = 12$. The shaded area in (a) denotes the photonic gap. Inset: Brillouin zone and symmetry points of the f.c.c. lattice.

Figure 2 Schematic plots of the Yablonovite (a) and woodpile (b) photonic structures.

Many other structures possessing a complete photonic gap in three dimensions have been studied. Two of them are shown in Figure 2. The structure in Figure 2a, called the “Yablonovite” (from the name of its proponent, E Yablonovitch) is obtained by drilling three sets of cylindrical holes with a triangular pattern, at 35.26° from the surface normal and at 120° with respect to each other. It represents a distortion of the diamond structure of air spheres in a dielectric material, where the surface is a $(1\ 1\ 1)$ plane of the crystal and the holes correspond to $[1\ 1\ 0]$ open channels of the diamond structure. The Yablonovite can be realized, in principle, at infrared and optical wavelengths by deep lithography. The structure in Figure 2b, often called “woodpile,” is obtained by stacking four alternate layers of dielectric rods: starting from a first layer, the second layer is rotated by 90° with respect to the first, and the third layer is shifted by $a/2$ (a is the lattice constant) with respect to the first one. The woodpile structure can be realized by a series of stacking steps. The fabrication procedures of Yablonovite and of woodpile are examples of “top-down” and “bottom-up” approaches, respectively.

Two-Dimensional Photonic Crystals

2D photonic crystals have a dielectric constant that is periodic in a plane (xy) and homogeneous in the third (z) direction. The most interesting situation is when light propagates in the xy plane, that is, for a vertical wave vector $k_z = 0$. The system is invariant under specular reflection with respect to the mirror plane xy ; thus the electromagnetic eigenmodes can be classified as even or odd with respect to this mirror symmetry. Even states have nonvanishing field components (E_x, E_y, H_z) and are called H - (or TE -) polarized modes, while odd states have nonzero field components (H_x, H_y, E_z) and are called E - (or TM -) polarized. Unlike in the 3D case, there is a strong polarization dependence of the photonic bands.

Most 2D structures that have been studied are based on a square or on a hexagonal Bravais lattice. In general, the most favorable situation for a complete photonic gap is to have a structure with the highest possible rotational symmetry: this helps in achieving an overlap between bandgaps along different directions of the Brillouin zone. The square Bravais lattice has a fourfold symmetry axis, while the hexagonal lattice has a sixfold rotational axis that is the maximum possible symmetry for periodic Bravais lattices. Higher rotational symmetries are possible for nonperiodic structures, such as quasicrystals.

Figure 3 shows two examples of 2D photonic bands in structures with a full bandgap for all directions and polarizations, namely the triangular lattice of air holes in a dielectric medium (Figure 3a) and the graphite or honeycomb lattice of dielectric pillars in air (Figure 3b). Both structures are based on the 2D hexagonal Bravais lattice. The triangular lattice of holes has a large gap between the first and the second H -band and a smaller gap between the second and the third E -band, which overlap in the region shown by a dashed area in Figure 3a. For the assumed value of the dielectric constant ($\epsilon = 12$), the H -gap is found to open for hole radii $r/a > 0.16$, while the E -gap opens only for hole radii $r/a > 0.4$; therefore, a polarization-independent gap exists only for relatively high values of the air fraction. The graphite lattice of pillars, instead, has two complete bandgaps between higher-lying bands. Notice that the graphite lattice of pillars supports a large gap between the second and third E -bands, which however does not overlap any H -gap.

As a general rule, structures with a connected dielectric lattice (like that of Figure 3a) tend to have larger gaps for H -polarization, while structures with disconnected dielectric pillars (like that of Figure 3b) tend to support larger E -gaps. This criterion, which can be traced back to Maxwell boundary conditions for the nonvanishing field components, is generally followed for both square and hexagonal Bravais lattices. The overlap of H - and E -gaps is a stronger condition that occurs only in a few cases, those shown in Figure 3 being the most common examples. In real systems, the complete gap shown in Figure 3a is easier to realize, because it is lower in frequency and less sensitive to disorder. For technological applications, a polarization-sensitive gap is often sufficient and the commonly used structure is the triangular lattice of air holes for smaller air fractions than shown in Figure 3a, in order to reduce radiation losses.

2D photonic structures can be defined by a top-down procedure based on lithography and etching. The prototype of a 2D photonic crystal is macroporous silicon, which is obtained by wet etching of Si in an electrochemical cell. It should be remembered that the photonic bands such as those shown in Figure 3, refer only to propagation in the xy plane: in a system that can be considered as homogeneous in the z -direction, the bands retain an out-of-plane dispersion and light is free to propagate in the vertical direction. This mechanism is exploited in a new class of optical fibers, which are known as holey- or photonic crystal fibers.

Photonic Crystal Slabs

In order to achieve a better control of light propagation, a 2D photonic structure can be embedded in a planar (slab) dielectric waveguide, thereby realizing a "photonic crystal slab." A few possible structures are shown in Figure 4. The theoretically simplest system is the "air bridge" (Figure 4a), which consists of a self-standing patterned dielectric membrane surrounded by air. The air bridge has the highest refractive index contrast between the core and the cladding. Figure 4b exemplifies the silicon-on-insulator (SOI) structure, consisting of an air/Si/SiO₂ waveguide in which only the Si layer is patterned. A system with a weak refractive index contrast is shown in Figure 4c, and it can be realized with GaAs/AlGaAs or with InP/InGaAsP waveguides: both the core and the cladding need to be patterned in order to maintain the guiding properties of the slab. The fabrication of photonic crystal slabs requires epitaxial growth, lithography, and dry (reactive-ion) etching steps.

Photonic crystal slabs are characterized by the light-line issue. Only photonic modes that lie below the light dispersion of the cladding material(s) in the $k - \omega$ plane are truly guided and stationary, while modes that lie above the cladding light line(s) are radiative and only quasi-guided. For a specified value of the in-plane wave vector, the truly guided modes lie in a frequency region of the discrete spectrum, while quasi-guided modes lie in the region of the continuous spectrum and appear as resonances: their line width can be related to an imaginary part of the mode frequency.

An example of mode dispersion in a photonic crystal slab is shown in Figure 5 and it refers to an air bridge patterned with a triangular lattice of holes. Figure 5a shows the real part of the frequency dispersion in the Γ -K direction. The cladding light line (dotted line in the figure) separates the regions of guided and quasi-guided modes. The planar waveguide is monomode up to a frequency $\omega a/(2\pi c) \cong 0.61$, where a second-order mode appears. $\text{Re}(\omega)$ is generally larger than for the ideal 2D case due to a vertical confinement in the slab waveguide: this effect is particularly pronounced for a strong index-contrast slab. Figure 5b displays the calculated reflectance of a plane wave incident on the surface of the slab, for increasing values of the angle of incidence. Spectral structures appear in reflectance spectra, which mark the excitation of photonic modes and whose evolution as a function of the incidence angle corresponds to the $\omega(k)$ dispersion of Figure 5a: the wave vector parallel to the surface is conserved and it equals $k = (\omega/c) \sin \theta$ (modulo a reciprocal lattice vector). Figure 5c shows the imaginary part of the frequency of quasi-guided modes

Figure 3 Photonic bands of (a) a triangular lattice of air holes with radius $r/a = 0.45$ in a dielectric material and (b) a graphite lattice of dielectric pillars with radius $r/a = 0.18$ in air. The dielectric material has $\varepsilon = 12$ in both cases. Solid (dashed) lines represent H - (E -) polarized modes: they are even (odd) with respect to a horizontal mirror plane. The shaded areas denote the photonic gaps. Insets: structures and 2D Brillouin zone.

plotted as a function of the real part. The imaginary part depends strongly on the mode index and on the wave vector, and it vanishes when the real part of the dispersion crosses the light line and goes into the guided mode region. It can be seen that an increasing imaginary part in Figure 5c corresponds to an increasing line width of the reflectance structure in Figure 5b.

The imaginary part of the mode frequency leads to an imaginary part of the wave vector through the relation $\text{Im}(k) = \text{Im}(\omega)/v_g$, where $v_g = d\omega/dk$ is the group velocity. Physically, a propagating quasi-guided mode in an ideal photonic crystal slab is subject to intrinsic radiative losses due to diffraction out of the 2D plane. In real systems, extrinsic diffraction losses related to fabrication aspects (insufficient hole depth, nonvertical profile, roughness of the sidewalls) are present for both guided and quasi-guided modes.

Defect States

It is well known in the electronic structure theory that localized defects introduce impurity states in the gap. An analogous phenomenon takes place in photonic crystals. A common example is a planar defect in a 1D photonic crystal, which is known as

Figure 4 Schematic plots of photonic crystal slabs: (a) air bridge, or self-standing membrane, (b) SOI, where only the Si core layer is patterned, and (c) AlGaAs/AlGaAs, where all layers are patterned.

a planar (or Fabry–Pérot) microcavity. Linear and point defects in photonic crystals of higher dimensionality also give rise to defect modes within the photonic bandgap. The simplest kinds of defects can be treated with the methods introduced for bulk photonic crystals, provided the defect is repeated with supercell periodicity.

An example of photonic bands for a line defect, or channel waveguide in a photonic crystal slab is shown in Figure 6. The structure consists of a single missing row of holes in the Γ –K direction of the triangular lattice (see inset). The defect modes are found outside the projections of the 2D bands onto the Σ –K direction, which are denoted by shaded regions. The defect mode that falls below the photonic gap of the triangular lattice is called “index-guided,” because it is laterally confined by the dielectric discontinuity between the channel region and the surrounding photonic crystal. The modes that exist only within the bandgap of the 2D lattice are called “gap-guided” and are laterally confined by the photonic gap, that is, by the lack of electromagnetic eigenmodes in the surrounding material. Both index- and gap-guided modes can be seen in Figure 6. Notice that the defect modes

Figure 5 (a) Real part of the frequency; (b) specular reflectance from the surface at angles of incidence from 0° to 80° in steps of 5° ; and (c) imaginary part of the frequency for a photonic crystal slab with a triangular lattice of air holes of radius $r/a = 0.3$ patterned in a membrane with core thickness $d/a = 0.3$ and dielectric constant $\epsilon = 12$. All curves calculated for TM polarized (even) modes with respect to the plane of incidence along the Σ –K orientation. Solid (dashed) lines in (a) and (c) correspond to even (odd) modes with respect to a horizontal symmetry plane. The dotted line in (a) represents the dispersion of light in air.

Figure 6 Dispersion of defect modes of a linear waveguide in a membrane with thickness $d/a = 0.3$ and dielectric constant $\varepsilon = 12$. The structure is shown in the inset and the holes in the triangular lattice have a radius $r/a = 0.36$. Only horizontally even and vertically odd modes are shown. The shaded regions correspond to the projected bands of the periodic lattice and the dashed lines denote the light dispersion in the dielectric material and in air.

can be either guided or quasi-guided, according to their frequency with respect to the cladding light line. Truly guided defect modes allow, in principle, for straight propagation without losses.

The linear defect structure in a photonic crystal lends itself to the realization of ultra-compact waveguides with sharp bends, which cannot be obtained with conventional dielectric waveguides based on total internal reflection. Figure 7 shows an example of wave propagation through a 120° bend in the triangular lattice of holes – the electromagnetic pulse is guided through the bend by the existence of a photonic gap in 2D. The FDTD method is particularly useful to model this kind of structures.

Measuring the Photonic Band Structure

In conclusion, a few experimental methods for measuring the photonic band structure are mentioned. The frequency window of a photonic bandgap can be obtained by transmission (or reflection) measurements. The conceptually simplest method for obtaining the photonic band dispersion in the direction of light propagation is to measure the phase delay $\varphi(\omega)$ of an electromagnetic wave through the photonic crystal: if d is the thickness of the sample, the wave vector at any given frequency can be obtained from the relation $\varphi(\omega) = k(\omega)d$. This method has been applied by means of phase-sensitive measurements, first in the microwave spectral region and later in the near infrared and visible regions. The band dispersion in the direction of light propagation can also be obtained by analyzing Fabry–Pérot fringes in reflection or transmission through a sample of finite size. The photonic dispersion in two or three dimensions can also be derived by measuring the beam propagation (i.e., the refraction) of a light beam impinging on the photonic crystal at nonnormal incidence. The 2D band dispersion above the light line in photonic crystal slabs can be obtained

Figure 7 Electric field profile for an electromagnetic wave propagating through a 120° bend designed in a triangular lattice of air holes (FDTD calculation in two dimensions). The modulus of the field is represented in a linear scale.

by variable-angle reflectance measurements from the crystal surface. The principle is apparent from Figure 5b: the spectral position of a resonant structure in reflectance yields both the frequency and the parallel wave vector of a photonic mode. The same variable-angle reflectance technique can be applied to 2D and 3D photonic crystals, and in this case, it leads to the dispersion of photonic bands in a plane parallel to the crystal surface. Finally, the photonic dispersion can also be obtained by angle-resolved luminescence measurements in the far field: this is the photonic analog of angle-resolved photoemission spectroscopy for electronic systems.

Introduction

The performance of a complex electronic circuit usually scales with the number of its components. In the early days of electronics, circuits were bulky assemblies of vacuum valves (invented by Lee de Forest in 1906), resistors, and capacitors fixed on a metal frame, and connected with soldered copper wires. The invention of the transistor by Bardeen, Brattain, and Shockley in 1947 already contained the seed of further circuit miniaturization, but it would take more than 10 years before this potential was fully recognized. In 1959, Jack Kilby from Texas Instruments and Robert Noyce from Fairchild independently filed patents for an electronic circuit whose components were fabricated on a single piece of semiconductor material (germanium for Kilby and silicon for Noyce). Kilby's circuit measured 0.2×0.8 inches and had 12 components, connected together with tiny gold wires. To quote his own words, "what we didn't realize then was that the integrated circuit would reduce the cost of electronic functions by a factor of a million to one, nothing had ever done that for anything before." Today, integrated circuits (ICs) may contain tens of millions of transistors per square centimeter. Jack Kilby received the Nobel prize for his invention in 2000 (Figure 1).

IC Materials

The vast majority of ICs are fabricated on single crystal silicon. Although not the best semiconductor material, silicon is still unrivaled thanks to its crystalline perfection, its excellent combination of electrical and thermomechanical properties, as well as the outstanding quality of its natural oxide, SiO_2 . For some low-cost applications where data speed is not an issue, polycrystalline silicon films deposited on glass can also be used. The most recent IC technology is silicon-on-insulator (SOI), which consists of a thin monocrystalline silicon film, isolated from the bulk silicon substrate by an intercalated SiO_2 layer.

Over the years, other substrate materials have found a role in niche technologies, targeting applications for which silicon is not the optimal choice. The most important IC technology after silicon is based on III–V compound semiconductors. Prominent among

Figure 1 (a) The first integrated circuit. (b) Jack Kilby contemplating a 300 mm silicon wafer with state-of-the-art ICs. (Courtesy of Texas Instruments.)

them is gallium arsenide (GaAs), which is a better semiconductor than silicon although less robust from a manufacturing point of view. Due to its high electron mobility and high bulk resistivity, it is the substrate of choice for high-frequency circuits. As a direct bandgap material, gallium arsenide is also an efficient light emitter and therefore well suited for optoelectronic devices, a domain where silicon cannot compete since its own bandgap is indirect. GaAs can be combined with indium, phosphorous, or antimony to tune the band structure for specific applications. Indium phosphide (InP), another III–V compound, is a convenient substrate for many epitaxial films made from ternary or even quaternary III–V alloys. A new player in this area is gallium nitride (GaN), well-suited for power electronics and optoelectronics. GaN is not available as a bulk substrate and must be grown on sapphire or silicon carbide (SiC). Together with SiC and diamond, it belongs to a special class of wide bandgap semiconductors, which are fit for high-voltage device fabrication. However, their present materials quality is lagging far behind silicon and the commercial future of these technologies is still unclear.

IC substrates are usually produced as circular wafers, a few hundred micrometers in thickness, cut from as-grown cylindrical ingots of various diameters. Silicon wafers are commercially available with diameters up to 300 mm, whereas other semiconductor substrates are significantly smaller. Silicon ICs can be classified into two groups based on the type of transistors they contain. Bipolar circuits use bipolar junction transistors as their principle elements. Metal oxide semiconductor ICs contain mainly *n*- and *p*-type metal-oxide semiconductor field-effect transistor (MOSFET) as their active components and are the dominant technology for logic circuits (i.e., processors and memories, also called digital circuits). Today, the most common architecture for digital electronics is complementary MOS (CMOS), which uses a combination of a *p*-MOSFET and *n*-MOSFET as its basic device to minimize the power consumption during switching.

IC Technology

The making of an IC typically proceeds through three standard stages: (1) fabricating individual devices, (2) wiring the devices together to form the circuit, and (3) encapsulating the IC in a package. The full sequence of the fabrication steps required to produce a complete circuit is called the process flow. Different IC technologies therefore require different process flows. In the following, the focus will be on CMOS technology because of its dominant position in the IC market.

Device Fabrication

Starting from a clean substrate, the first stage of IC fabrication – commonly called front-end process – is to form individual devices. The devices are produced through several levels of patterning, each level consisting of a well-defined combination of photolithography, deposition and etching steps. For a MOSFET, the typical front-end sequence is the following:

1. doping and isolation of the transistor wells and junctions
2. growth of the gate insulator
3. patterning of the gate electrode
4. formation of the metal contacts

In total, a CMOS process may require several hundred individual steps. The most important ones are outlined below.

The transistor well

The well is the region of the substrate containing the transistor body. Since current must pass through the device, the well must be doped to provide charge carriers (electrons or holes). After the device area has been delineated by photolithography and isolated from its surroundings by thin grooves (so-called shallow trenches), etched into the substrate and filled with a dielectric material, dopants are introduced into the well region. For *n*-type MOSFETs, the well must be *p*-doped whereas *p*-MOSFETs need *n*-doped

wells. In the early days of MOS technology, diffusion of impurities from a gaseous or solid-state source was the standard doping technique. However, with present deep-submicron device dimensions, this method has been replaced by ion implantation, which offers far better flexibility, precision and depth control. Ions of boron (for *p*-type), phosphorous or arsenic (for *n*-type) are accelerated by an electric field and gain a kinetic energy of a few tens of kiloelectronvolts, allowing them to penetrate some hundred nanometers into the substrate. Several implantation steps are usually required to reach the desired dopant profile. The as-implanted region has high electrical resistance due to the radiation-induced lattice damage, which can range from isolated point defects to complete amorphization. The high defect density prevents the dopants from occupying substitutional lattice sites, thereby leaving them electrically inactive. In order to activate the dopants, damage must be removed by a high-temperature annealing step (typically between 800 and 1000°C). This can be done in a conventional furnace, but a short thermal pulse produced by halogen lamps (the so-called rapid thermal process or RTP) is often preferred in order to minimize the motion of the implanted species during annealing.

The gate insulator

The thinnest feature of the transistor is the gate insulator, which consists of a few nm of silicon dioxide (SiO_2) deposited directly on top of the transistor well. The gate oxide is formed by thermal oxidation of the silicon surface, which involves heating the substrate above 900°C in an oxygen atmosphere (dry oxidation) or a mixture of oxygen and water (wet oxidation). Trace amounts of other gases are often added to improve the electrical quality of the oxide. Both the temperature gradients and the gas flow pattern in the furnace must be accurately controlled to obtain a very thin and uniform oxide. Short thermal pulses produced by rapid thermal processing can also be used. Although the as-grown oxide layer is structurally amorphous, the high quality of its chemical bonds with the silicon surface limits the density of interface defects to very low levels (less than 10^{10} cm^{-2}). The quality of the gate oxide and of the Si/ SiO_2 interface is a crucial factor to ensure the good electrical behavior of the MOSFET. However, there are now indications that further shrinking of the devices will push SiO_2 toward its application limit. For very thin oxides, direct carrier tunneling through the gate insulator produces a sizable current leakage and unwanted power dissipation. This problem can, in principle, be overcome by introducing “high-*k* insulators,” that is, gate dielectrics with a higher polarizability than SiO_2 . These materials would allow the physical thickness of the insulator to increase (thereby keeping tunneling currents at an acceptable level), while maintaining a strong capacitive coupling between the gate and the channel. At this time, refractory metal oxides such as HfO_2 as well as some ferroelectrics are potential candidates for replacing silicon dioxide in future ICs.

Gate, source, and drain

The gate electrode sits on top of the oxide and regulates the current inside the transistor channel. It is made of doped polycrystalline silicon (usually designated as “poly”), which is a reasonably good conductor and can be patterned into very narrow lines. Today, the most advanced commercial transistors have a physical gate length of ~50 nm. Since the gate is the narrowest feature on any IC, its formation involves the most demanding steps of the front-end process flow. First, a blanket layer of poly is deposited by chemical vapor deposition (CVD), after which the gate fingers are defined by a lithography step and patterned by dry etching. In order to achieve the right threshold voltage for the transistor, the poly-gate on the NMOS is *n*-doped whereas on PMOS it is *p*-doped. Both doping steps are performed by ion implantation and annealing. In a MOSFET, the current input and output electrodes are called source and drain. They are defined by local implantation of complementary doping species (*n* for *p*-well and *p* for *n*-well) very close to the surface, thereby forming shallow *p*-*n* or *n*-*p* junctions, depending on the transistor type. Fine-tuning of the junction profiles requires additional implantation steps followed by annealing.

Contacts

Metals are needed for electrical contacts to the three device electrodes. The contact material must exhibit low electrical resistance and be chemically compatible with silicon in order to avoid interface degradation over time. For many years, metal silicides have been used extensively on the source and the drain: first titanium disilicide (TiSi_2), and more recently cobalt disilicide (CoSi_2) and nickel monosilicide (NiSi). The silicide layers are formed by solid-state reaction of a deposited metal film with the underlying silicon; therefore, it is important that the reaction should not consume too much silicon. In the same way, a polycrystalline silicide layer or polycide is formed on top of the poly in order to contact the gate electrode and to reduce the gate series resistance (Figures 2 and 3).

Interconnects

Connecting the individual transistors is an essential step in the production of an IC. The process flow needed for interconnect fabrication is called the back-end sequence. Since the early days of IC technology, aluminum-based alloys have been used as the interconnect metal. This choice was dictated by the low resistivity of aluminum, its high ductility, easy etching behavior, and good coverage of nonplanar geometries. The latter property is particularly important, since complex ICs normally require many levels of wiring stacked on top of each other, giving rise to a multilayer structure called the multilevel interconnect scheme. To improve the electrical reliability of the wires, particularly with respect to electromigration, aluminum-silicon and aluminum-silicon-copper alloys are preferred over pure aluminum. However, in the late nineties the series resistance of aluminum-based lines became a bottleneck for circuit performance. After more than 30 years of use, the aluminum wires were finally abandoned in favor of a copper-based metallization scheme. Copper conducts about 60% better than aluminum, but patterning it into submicron wires is difficult because traditional plasma etch techniques do not work on copper. A novel process called “damascene” had to be

Figure 2 Schematic process flow for an MOS transistor.

introduced, due to its similarity with the well-known metal inlaid technique that goes back to the Middle Ages. Following this process, the conductor wires are embedded in a dielectric film deposited on the silicon substrate or on a previous interconnect layer. Copper lines are formed by electroplating the metal inside preformed trenches, which have been etched into the dielectric. The formation of a multilevel damascene scheme requires special polishing techniques (called chemical mechanical polishing or CMP) to planarize each interconnect layer by removing the excess metal outside the trenches (Figure 4).

Figure 3 Cross-sectional scanning electron microscopy picture of an integrated MOS transistor. (Courtesy of IMEC.)

Packaging

Packaging the IC serves a twofold purpose: to protect the chip against mechanical damage and corrosion, and to provide electrical connections with the outside circuitry. An IC package consists of a sealed box which is either from ceramic material (for hermetic sealing) or from a plastic mold (for low-cost packaging). Metallic pins are attached to the base plate of the package, to be inserted in the printed circuit board. After completing the back-end process, the backside of the chip is fixed to the package base plate using a

(a)

Figure 5 IC in package. (Courtesy of IMEC.)

conductive paste or metal solder. Next, the bonding pads of the chip are connected to the package pins. The most common technique is wire bonding: thin aluminum or gold wires are thermally bonded to the IC pads and to the pins, sometimes with the help of ultrasonic vibrations. Wire bonding is cheap and reliable, but cannot handle the increasing density of bonding pads in the most recent IC generations. Flip-chip bonding is now an increasingly popular alternative. Microscopic solder balls are first deposited on the IC bonding pads. The chip is then positioned face down to the package base plate, so that the solder balls can be attached directly to the pin pads. Since this method does not use wires, it offers both higher connection density and better reliability than the traditional bonding schemes. After wiring, the upper lid of the package is sealed or molded to the base plate for final encapsulation (Figure 5).

Processing Techniques

Photolithography

Photolithography uses a beam of photons to transfer a pattern written on an optical mask to the substrate surface. In a complex IC process, a wafer will go through the photolithographic step in the order of 20–30 times. Photolithography is, therefore, the key technology of IC fabrication and an essential driver behind the miniaturization trend commonly known as Moore's law. It was introduced almost simultaneously with the invention of the IC in 1959, but in the meantime, the minimum dimensions on the masks have decreased by several orders of magnitude, forcing continuous improvement in lithography tools and processes.

A standard lithography sequence involves a large number of steps. The wafer is initially cleaned and heated to remove any moisture from its surface. After deposition of an adhesion promotor, a liquid polymer called photoresist is spun on the surface while the wafer is kept rotating at high speed. After a thermal bake-out, the substrate is introduced in an optical projection tool called stepper/scanner. A light beam passing through the mask is focused on the wafer through a reduction lens system to produce the desired image in the photoresist. In order to achieve high resolution, only a small portion of the mask is imaged once, but the small image field is repeated over the surface of the wafer by a combination of stepping and scanning operations. During exposure, the photoresist material undergoes some light-triggered chemical reactions, which cause the illuminated regions to be either more or less acidic. If they become more acidic, the material is called a positive photoresist, while in the reverse case it is a negative photoresist. The resist is then developed in an alkali solution such as sodium hydroxide (NaOH), which removes either the exposed (positive photoresist) or the unexposed (negative photoresist) polymer. After development, the wafer is finally "hardbaked" at high temperature in order to solidify the remaining photoresist. The resist can then be used as a patterning mask for etching, deposition or implantation. After patterning, the resist is stripped from the wafer with appropriate solvents.

The optical resolution of the lithography system is the main factor determining the smallest device size that can be fabricated at any time. The ability to form a clear image of a very small feature is limited by the wavelength of the light and the ability of the lens system to capture enough diffraction orders of the illuminated mask. Although theoretically the Rayleigh diffraction limit determines the maximal achievable resolution, in practice, it is possible to use special (but costly) tricks called resolution enhancement techniques that improve resolution beyond the Rayleigh limit by a factor of 2 or more. Current state-of-the-art photolithography tools use deep ultraviolet light (DUV) with wavelengths of 248 and 193 nm, allowing feature sizes below 100 nm to be printed with good yield. Extreme ultraviolet (EUV) systems using 13 nm radiation are presently under development for

introduction by the end of this decade. Because such short wavelength radiation cannot be diffracted by lens systems or absorbed by bulk masks, the EUV technology will require a transition from diffractive to fully reflective optics.

Dry Etching

The aim of the etching process is to remove material from the IC surface in the areas left uncovered after photoresist development. For most patterning steps, dry (plasma) etching is now the standard procedure, while “wet” etching using liquid chemicals is still used to clean wafers. The main advantage of dry etching is its ability to achieve sharp etch profiles with nearly vertical sidewalls. This creates features with a high aspect ratio, as required by the relentless miniaturization of the circuit elements. A hot plasma formed by RF excitation of a neutral gas species is directed on the wafer by a static electric field. The radicals in the gas react with the substrate material to form volatile byproducts which are either evacuated from the etch chamber or deposited on the chamber walls. The mixture normally consists of a hydrogenated hydrocarbon diluted in an inert gas. However, the gas composition depends on the material to be etched, and will be different for silicon, metals or SiO₂. The strength of the DC field also plays a role in the etch process. A strong field increases the kinetic energy of the ions, and therefore enhances the amount of physical etching, which depends on mechanical sputtering. On the other hand, low-energy ions will act essentially by chemical etching, which proceeds through surface reactions resulting in smoother patterns. In this way, the etching mechanism can be tuned to optimize the shape of the patterned structures.

Deposition Techniques

PVD

In standard silicon processing, physical vapor deposition (PVD) uses target sputtering rather than target evaporation because of its better step coverage. For aluminum interconnect layers, plasma-induced sputtering is the most convenient technique. The sputtered metal lands on the wafer surface where it forms a thin metal film, which can be further etched into wires. The film thickness is proportional to the width of the conductor lines, and usually lies in the range of a few hundred nanometers. Plasma sputtering can also be employed to deposit nonmetallic layers, especially insulators, although for the latter, CVD is the preferred method.

CVD

Chemical vapor deposition is a process by which a thin film is deposited on a substrate by chemical reaction in a gas at an elevated temperature. If required, the reaction temperature can be lower by using plasma-enhanced CVD (PECVD). Over the years, CVD has become very popular due to its versatility, speed of deposition, and excellent step coverage. CVD can be used for metal, semiconductor, and insulating films. The structure of the deposited film can be monocrystalline, polycrystalline, or amorphous. The lattice structure depends primarily on the substrate, the reaction rate, and the temperature. Selective deposition is also possible, by choosing precursor gases that react preferentially with specific surfaces. CVD is the preferred method to deposit polycrystalline silicon, as well as various types of oxide films used for isolation of the interconnect layers. These interlayer dielectrics are grown by CVD at low pressure (LPCVD). Thin metallic layers such as titanium nitride (TiN), which are used as seed layers for copper electroplating or as a seal between the interlayer dielectrics, are also deposited by CVD.

Epitaxy

Epitaxy is a process by which a deposited film is forced into a high degree of crystallographic alignment with the substrate lattice. Several epitaxy techniques are now available, such as molecular beam epitaxy (MBE), epitaxial CVD, or atomic layer epitaxy (ALE). In all cases, the deposition process must be slow enough to allow the atoms to rearrange themselves on the surface according to the lattice orientation of the substrate. Contamination of the surface by impurities must be kept minimal, since it will disturb the epitaxial alignment. Epitaxial layers are now widely used in IC technology and the number of applications is still growing. In the early days, the epitaxy process was limited to deposition of silicon on silicon (homoepitaxy). Today, an increasing number of devices require thin film hetero-epitaxy, for example, growing a binary alloy such as silicon-germanium (SiGe) epitaxially on the silicon wafer. For layers with high Ge concentration, the epitaxy is made difficult by the lattice mismatch between the substrate and the thin film. However, using appropriate techniques, the epitaxial layer can be grown pseudomorphically, meaning that the distance between the film atoms will adapt itself spontaneously to the bond length of the substrate material.

Physics of Integrated Circuits

Integration Density: Moore's Law

Moore's original statement, made in 1965, was modestly presented as an educated guess at the expected development of ICs over the next ten years. Or, to put it in his own words: “With unit cost falling as the number of components per circuit rises, by 1975 economics may dictate squeezing as many as 65,000 components on a single silicon chip” (see Further Reading Section). Almost four decades later, unit cost is still falling with the number of components, and as long as this favorable trend persists, the “law” will remain firmly in place. The continuation of Moore's law is made possible by the relentless shrinking of the MOSFET dimensions. Now, spanning more than two orders of magnitude, the downscaling of the MOSFET is a truly unique occurrence in the history of technology. The physical base for this miniaturization is a set of scaling rules defined some years after Moore's initial paper.

In essence, the scaling algorithms tell us that the transistor performance (mainly its gate delay time and overall power dissipation) will improve with decreasing dimensions, provided the rules are properly applied. However, a point has been reached where the presence of nonscaling quantities such as the thermal voltage kT/q and the semiconductor bandgap (together with some others) can no longer be neglected. These nonscaling parameters are giving rise to so-called “short-channel” effects, such as threshold voltage shifts and many others, which tend to degrade the transistor switching speed and lower its power efficiency. These disturbing effects can be acted upon with specific counter-measures, partly technological and partly design-related. Up to now, device engineers have been remarkably successful in alleviating the negative impact of short-channel effects. However, it appears increasingly difficult to define a universal approach similar to the early scaling laws, and a certain amount of specialization in the circuit technologies (such as distinguishing between high-speed and low-power applications) is becoming unavoidable.

Speed and Power

Power and speed issues are strongly linked by the scaling rules. The width, length, and gate oxide thickness all scale roughly equally by a common factor. Therefore, the primary effect of the device scaling is to reduce all the capacitances, which provides a proportional decrease in power consumption and RC delays. However, not all the vertical dimensions of the circuit scale down by the same factor. In particular, the thickness of the interconnect lines cannot change as fast due to fundamental technology limitations. This increases the fringe capacitance from the metal side to the substrate, as well as the capacitance between adjacent line segments. Compounding this problem, the decreasing wire width raises the series resistance of the lines. As a result, RC delays in the lines tend to become more important with respect to transistor delays. This can be counteracted by optimizing the interconnect layout, and by introducing low- k dielectrics as the insulating layers between the copper wires.

The scaling rules also impact on the power consumption of the IC. There are two main sources of power dissipation: dynamic switching power due to the charging and discharging circuit capacitances, and static dissipation from leakage currents. When CMOS devices switch, the output is either charged up to the transistor bias voltage, or discharged down to the ground. The power dissipated during switching is therefore proportional to the switching speed and to the capacitive load. Decreasing the clock frequency of the circuit is, therefore, an efficient way to lower the dynamic power consumption.

Static power dissipation is linked with two types of leakage currents: reverse-bias diode leakage on the transistor drains, and subthreshold leakage through the channel when the transistor is turned off. Diode leakage must be tackled through process optimization, mainly by improving the quality of the junctions. Subthreshold current is a more complex issue. The process parameter that predominantly affects its value is the threshold voltage, since reducing the latter exponentially increases the subthreshold current. Static power dissipation can, however, be reduced by shrinking the transistor size, and by lowering the supply voltage.

Applications

Most ICs belong to one of three main categories: memories, microprocessors, and custom ICs.

Memories

Random-access memory (RAM)

A type of computer memory that can be accessed randomly; that is, any byte of memory can be accessed without disturbing the other bytes. RAM is the most common type of memory found in computers and other information processing devices. There are two basic types of RAM: dynamic RAM (DRAM) and static RAM (SRAM). Both are volatile memories, meaning that they lose their contents when the electrical power is turned off. RAM circuits are organized in cells, with each cell storing a binary 1 or 0. DRAM cells are very simple, consisting basically of one transistor and one capacitor for charge storage. Because this capacitor leaks, a DRAM needs to be refreshed thousands of times per second. This makes DRAM relatively slow and power-hungry. However, due to the small cell size, DRAM is best-suited for high-density storage (Figure 6). SRAMs are more complex, with 4–6 transistors per cell, providing a stable storage, which does not need to be refreshed. SRAM is very fast and power-efficient, but the complexity of its cell makes it much more expensive than DRAM. Due to its high cost, SRAM is used mainly as a memory cache.

Read-only memory (ROM)

Computers almost always contain a read-only memory that holds instructions to boot the operating system and perform diagnostics. ROM is nonvolatile, that is, it does not need electrical power to keep its data stored. Like RAM, ROM memories are random-access, but they cannot change their content during the computer operation. However, some types of ROM allow changing the content by special procedures. The most common ones are erasable programmable read-only memory (EPROM), electrically erasable programmable read-only memory (EEPROM) and FLASH EEPROM. FLASH (not an acronym) memories, which store the information bits in a second transistor gate called the floating gate, have become increasingly popular in recent years. They can be erased and reprogrammed in blocks instead of one byte at a time, which is faster and less power consuming than other EEPROMs. PCs have their basic input-output system (BIOS) stored on a flash memory chip so that it can easily be updated if necessary. Flash memory is also very common in communication appliances and portable devices such as cellular phones and smartcards.

Figure 6 Moore's law in action: evolution of the chip area / bit for a standard DRAM memory cell.

Microprocessors and Custom ICs

Microprocessors

Also called central processing unit (CPU), microprocessors are ICs that can execute instructions by running a software program. Although computer microprocessors have become a benchmark for the IC industry, they only represent a small part (~2% in unit sales) of the total CPU market. By far, the largest, by number, are the embedded microprocessors (also called microcontrollers), which can be found in many consumer products, ranging from toys to automobiles.

Custom ICs

In contrast to standard memories and microprocessors, custom ICs are specially designed for specific product applications. The main types are:

- *Application-specific ICs (ASICs)*. They are meant to achieve optimal performance in terms of speed and/or power consumption. ASICs are custom-designed for a specific application, either full custom (meaning that the design is made from scratch) or starting from standard cells or gate arrays, where the designers can take advantage of pre-existing blocks.
- *Field-programmable chips*. These are special chips that can be reconfigured by the customer. The most popular ones are field-programmable gate arrays (FPGAs). Their circuits are diced into regular arrays, which can be disconnected by blowing microscopic fuses. In this way, the desired functionality is "burned into" the IC. This process is reversible, meaning that the original connections can be restored and a new pattern burned. Although FPGAs are usually slower and less power-efficient than ASICs, they have become very popular due to their flexibility and ease of programming.
- *Analog/RF ICs*. Even if digital signal processing today represents the largest market for the semiconductor industry, there is also a wide variety of ICs handling analog and high-frequency signals. Some chips process both digital and analog information and are called mixed-mode ICs. Typical applications are amplifiers, mixers, multiplexers, and analog-to-digital converters. Wireless communication devices make heavy use of these components, which can be found in every cellular phone set.

Introduction

Semiconductor devices are key devices in modern electronics, and are roughly categorized into electronic devices and optical devices. The main applications as electronic devices are junction diodes, transistors, and memories, which are widely used in large-scale integrated circuits (LSI), as well as power devices such as thyristors and so on. As optical devices, light emitting diodes (LEDs), laser diodes (LDs), and photo detectors (PDs) are utilized in optical display and communication systems, while solar cells are important for energy conservation. In the following sections, the basic principles of these devices are described.

Junction Diodes

A junction of *p*-type and *n*-type semiconductors makes a diode structure as shown in Figure 1. Electrons or holes are the majority carriers in the *n*-type or *p*-type semiconductor, respectively. In the thermal equilibrium condition, the electrons in the *n*-type region near the *p*–*n* junction interface diffuse toward the *p*-type region because of the concentration gradient, and the holes in the *p*-type region diffuse vice versa. Then a depletion region or a space charge region, where no free carriers exist, appears. If one assumes an ideal *p*–*n* junction, which is very abrupt and the depletion completely occurs as shown in Figure 2, the built-in potential V_{bi} that appears across the junction is given by

$$V_{bi} = \frac{1}{2} E_m (x_p + x_n)$$

where

$$E_m = \frac{qN_A x_p}{\epsilon_s} = \frac{qN_D x_n}{\epsilon_s}$$

and the depletion region width W is given by

$$W = \sqrt{\frac{2\epsilon_s}{q} \left(\frac{N_A + N_D}{N_A N_D} \right) V_{bi}}$$

(here, q is the unit charge and ϵ_s is the dielectric constant).

When a positive bias V is applied to the *p*-type region with respect to the *n*-type region, the holes in the *p*-type region easily move into the *n*-type region, and the electrons in the *n*-type region move in the opposite direction. Thus a large current flows across the junction. Such a bias condition is called a forward bias. When, on the other hand, the bias condition is inversed, which is called a reverse bias, the majority carriers are not able to move at all. Then the total current density J flowing across the junction is given by $J = J_s (e^{qV/kT} - 1)$, where J_s is the saturation current density, k is the Boltzmann constant and T is the temperature. Therefore, the diode has asymmetric current–voltage characteristics against the bias voltage V as shown in Figure 3, and the diode device achieves a rectification property for alternating currents. This rectification effect in the *p*–*n* junction is very important in most semiconductor devices because it can control the current flow by blocking undesirable current leakage. In the real *p*–*n* junction diode, however, a voltage breakdown occurs at a high reverse bias, which gives the reverse bias tolerance of the diode, also shown in Figure 3.

Figure 1 A schematic illustration of a p - n junction diode.

Bipolar Transistors

The bipolar transistor which was invented by a research group at Bell Laboratories in 1947 has become one of the most important semiconductor devices today. It consists of two p - n junctions, that is, p - n - p or n - p - n structures as shown in Figure 4. These three regions are called emitter, base, and collector. In the symbols of the p - n - p and n - p - n transistors, the arrow indicates the direction of current flow under normal operating conditions, where forward and reverse biases are applied to the emitter-base and collector-base junctions, respectively. The specific features in the bipolar transistor are the very thin base and the highly doped emitter. The latter brings a high injection of carriers into the base region, where the injected carriers become the minority, while those carriers pass through the base region into the collector with a very small recombination rate owing to the former feature. Therefore, the collector current I_C can be represented by the emitter current I_E as $I_C = \alpha I_E$, where α is slightly less than 1. In general, a forward bias V_{EB} is applied to the emitter-base junction, but the collector-base bias V_{CB} is in a reverse bias condition. Since the collector junction is highly and reversely biased, the power amplification against the input power to the emitter junction is achieved. In the following discussion, the p - n - p transistor is considered but an appropriate change of polarities makes the results applicable to the n - p - n transistor. The basic model for the bipolar transistor is the Ebers-Moll model, in which the transistor is represented by two diodes connected face to face and two current sources. A circuit diagram in the Ebers-Moll model for the p - n - p transistor is illustrated in Figure 5. In this model, a current I_R flowing through the collector-base diode determines a current value from the current source in the emitter side, and a current I_F through the emitter-base diode determines a current from the current source in the collector side. Here, amplitudes of current gain α_R and α_F that are barely less than 1.

There are three configurations of the bipolar transistors as shown in Figure 6. In the common-base configuration, where the base lead is used as a common terminal for input and output, a signal is inputted to the emitter-base junction that is forwardly biased, while a load resistance is connected to a side of the reversely biased collector-base junction to extract an output signal. The common-base configuration is suited for a low input impedance circuit. According to the Ebers-Moll model, the collector current I_C is given by $-\alpha_F I_E$ because I_R is almost zero. In this configuration, therefore, only voltage amplification is obtained without current amplification. On the other hand, the common-emitter configuration, in which the emitter lead is used as a common terminal, is most widely used, and the current amplification as well as the voltage amplification is achieved because the collector current I_C is given by $I_C = \alpha_F I_E / (1 - \alpha_F)$ and the collector-base junction is still reversely biased. On the contrary, the common-collector configuration gives only a current gain without the voltage amplification, which is useful as an impedance converter. The typical output characteristics for the bipolar transistor in the common-base and common-emitter configurations are illustrated in Figure 7.

Since a current density strongly depends on the p - n junction cross section, and a switching speed is determined by the base region thickness in the bipolar device, they can easily be improved by using a large junction cross section and a thin base region, respectively. Therefore, bipolar devices are also suited for high speed and/or power devices. The three p - n junctions in series, such as p - n - p - n or n - p - n - p structures, are used in three- or four-terminal devices, in which bistable operations with low-power dissipation is possible. These devices are called thyristors and are applicable in high-current, high-voltage, or high-power switching devices.

One may change one or all the lead materials in the bipolar devices in order to be different from others as shown in Figure 8; such devices are called heterobipolar devices. In heterobipolar devices, many performances are well improved. For instance, (1) high-emitter efficiency owing to the blockade of the hole injection (the minority carrier injection for the emitter) from the base into the emitter by the high barrier in the valence band, (2) low-voltage drop at the emitter-base junction, and (3) high-frequency response owing to a high-current gain and low-base resistance because heavy doping in the base region is possible without degrading emitter efficiency.

Figure 2 (a) Space charge distribution, (b) electric field distribution, (c) potential variation, and (d) energy band diagram of an ideal p - n junction in thermal equilibrium condition.

Field Effect Transistors

Similar to the bipolar transistor, a field effect transistor (FET) has three terminals, called source, gate, and drain. There are some variations of FET structures as illustrated in Figure 9. In the junction FET (JFET), which was the first proposed of all FET devices, the gate bias voltage varies the depletion region width at the p - n junction under the gate to control a channel conductance. In the metal-semiconductor FET (MESFET), a Schottky junction is formed between a gate metal and a channel semiconductor, and the depletion width is varied by the gate voltage. On the other hand, a metal-insulator-semiconductor (MIS) structure, in which an insulator film is inserted under the gate electrode to prevent current leakage between the gate and the channel, is suited for FET devices. Especially, silicon dioxide is widely used as an insulator in silicon FETs, which are called metal-oxide-semiconductor FET (MOSFET). In contrast to the bipolar transistor in which both positive and negative charges play important roles, only unipolar charges flow in the FET channel. Thus the FET is classified into either an n -channel or a p -channel FET. It is also possible to categorize MOSFET by the conductivity at zero gate bias into a normally-off type or a normally-on type as shown in Figure 10. If the channel conductance is very low at the zero gate bias and a positive bias to the gate is required to form a conductive n -channel, this type is called the normally-off (or enhancement) n -channel MOSFET. The MOSFET, in which the n -channel is sufficiently conductive even

Figure 8 A schematic of the n - p - n heterobipolar transistor.

at the zero gate bias and one has to apply a negative bias to the gate to reduce the channel conductance by depleting the channel carriers, is the normally-on (or depletion) n -channel MOSFET. Similarly, there are the normally-off (enhancement) and normally-on (depletion) p -channel MOSFETs.

Now, a complementary use of the p -channel and n -channel MOSs in series, for instance, the normally-on p -channel and the normally-off n -channel MOSs, forms a complimentary MOS (CMOS) configuration as shown in Figure 11. In the CMOS, a low-input voltage (typically, $V_{low}=0\text{ V}$) keeps the n -channel enhancement MOS (normally-off) in the “off-state” (highly resistive) and the p -channel depletion MOS (normally-on) in the “on-state” (highly conductive). Therefore, an output is equal to the high source voltage. In contrast, a high input (typically, $V_{high}=5\text{ V}$) turns the n -channel MOS into an “on” state and the p -channel MOS into an “off” state, and therefore, the output becomes low level. Thus an inverter operation is realized by the CMOS configuration. In addition, a steady current passing through both the n -channel and p -channel MOSs can be sufficiently suppressed and the passing current only flows at the switching period, resulting in a very low power consumption in the circuits. Moreover, since the FET suits a planar configuration, CMOS transistors are mostly used in an integrated circuit (IC) or LSI.

By using compound semiconductor hetero-structures and a modulation doping technique, a high electron mobility transistor (HEMT) was realized as shown in Figure 12. The potential confinement of electrons at the heterointerface gives rise to a two-dimensional electron gas (2DEG). In the 2DEG system, the electron scattering probability is reduced because the states that the electrons can occupy are limited. In addition, the modulation doping also reduces the electron scattering rate by impurities because of a spatial separation between the conducting electrons and the impurities. Owing to these two effects, very high electron mobility is achieved in the HEMT device. Consequently, the HEMT device is practically used in high-speed applications.

Figure 9 Some variations of the FETs; (a) a JFET, (b) a MESFET, and (c) a MISFET. In the case of using an Si dioxide film as an insulator, the FET is specially called a MOSFET.

Memories

Another key device for the LSI circuits is a memory device. A conventional memory cell needs capacitors, in which data are stored as charges, and the memory devices can be categorized into volatile and nonvolatile types. The volatile memory allows a very high access rate though it consumes a large quantity of power for keeping data, a typical device of which is a dynamic random access memory (DRAM). The DRAM, therefore, is suited for main memories in the LSI circuits. In order to integrate a lot of DRAMs in the LSIs, a deep-trench structure is used for keeping capacitance sufficiently large. In the nonvolatile one, on the other hand, the access time is relatively long but data can be kept without power consumption; typical devices are floating gate RAM (FRAM) and static RAM (SRAM), which are applied to mobile telephones, for instance.

In most of the cases, the memory is fabricated by the compatible process of CMOS technologies. To access the memory, charging or discharging the capacitor is done for writing or reading, respectively, through the transistor connected to an addressing line.

Figure 10 Four basic types of MOSFETs at zero gate voltage.

Figure 11 (a) A schematic of the CMOS structure, and (b) its equivalent electrical scheme.

Figure 13 shows a one-bit memory cell in the simplest DRAM. For writing, the transistor channel is opened by an appropriate bias applied to the addressing line with a high bias applied to the data line, and subsequently the capacitor C_s is charged. For reading, on the contrary, the transistor channel is also opened and a voltage appearing in the data line is detected. If the capacitor has been charged, a certain value of voltage appears, while no voltage appears when no charge has been stored in the capacitor. These two states correspond to "1" and "0" as one bit in the binary logic.

Photodetectors and Photodiodes

Semiconductor photodetectors can detect optical signals through electronic processes. Light incident on a semiconductor excites electrons from the valence band to the conduction band, if the photon energy of the incident light exceeds a semiconductor bandgap energy, and, then, a current or a voltage is generated in the semiconductor. Thus, the photodetector acts as a current source or a voltage source under the light illumination.

Figure 12 (a) A device structure, and (b) an energy band diagram of the HEMT realized by using the semiconductor heterostructures.

Figure 13 A schematic of a one-bit memory cell in the simplest DRAM.

Generally, photodiodes consist of p - n or p - i - n (i means an intrinsic layer) structures. An electric field, existing at the depletion region around the p - n interface or the intrinsic region, is very important to separate photogenerated electron-hole pairs. The thin depletion region leads to a high-speed operation but low quantum efficiency (a ratio of the generated electron-hole pairs to the incident photons), while the thick one leads to the opposite. The basic operation mode of the p - i - n photodiode is illustrated in Figure 14. When the reversal bias applied to the p - i - n structure enhances a separation rate of the photogenerated electron-hole pairs, a high-speed operation is possible even if the depletion region is thick enough to achieve a high quantum efficiency. Especially, when a very high electric field is applied in the thick intrinsic region, secondary ionization occurs and thus the number of electrons and holes dramatically increases, resulting in quite high efficiency, which is called an avalanche photodiode (APD).

Figure 14 Basic operation mode of the $p-i-n$ photodiode.

The detectable wavelength range of the photodiode is an important parameter. The long-wavelength cutoff is determined by the bandgap of the semiconductor material used in the photodiode because of the lower photon energy light, which means that a wavelength, longer than the bandgap cannot be absorbed in the semiconductor. On the other hand, the absorption coefficient for a short-wavelength light is quite high, so such a light is absorbed very near the surface. Since, the carrier recombination occurs very frequently via the surface states, most of the photocarriers recombine without either being collected in the $p-n$ junction or contributing to the current. This limits the short-wavelength cutoff in photodiodes.

Solar Cells

A similar $p-n$ diode structure in the photodiode can be used as a solar cell, which works as an electricity source. In particular, a detectable wavelength range in the solar cell is well optimized to fit the spectrum of sunlight. The photocarriers generated in the $p-n$ diode are extracted as a current source, while photovoltage appears between the p - and n -type semiconductor ends due to the photocarrier separation. A current-voltage curve in the $p-n$ diode changes under the light illumination as shown in Figure 15. The property of the solar cell is characterized by three important parameters; the short-circuit current I_{SC} , the open-circuit voltage V_{OC} ,

Figure 15 Typical current-voltage characteristics in the $p-n$ solar cell with or without the light illumination.

and the maximum power rectangle P_M . High I_{SC} and V_{OC} , resulting in large P_M , are desirable. Since the photoabsorption spectrum of Si material matches the incident sunlight spectrum to some extent, Si is one of the best materials for solar cells. Si solar cells have already been used as alternative energy resources in both high- and low-power applications.

Light Emitting Diodes

When the electron–hole pair disappears by recombination, it should convert its energy to other constituents because of the energy conservation law. In direct transition semiconductors such as GaAs, photons whose energy corresponds to the recombination energy are emitted, while phonons are emitted, in most cases, in indirect transition semiconductors, and the semiconductor materials are heated. Especially where electrons and holes are intentionally injected from electrodes, a current–light conversion is achieved in the direct transition semiconductors. The p – n or p – i – n diode structures are suited for devices similar to photo detectors, and they are called LEDs. The electrons supplied from the n -type region and the holes from the p -type region recombine near the p – n interface or in the intrinsic region with light emission as illustrated in Figure 16. Since most electrons and holes distribute at the conduction and valence band edges, respectively, the emitted photon energy is almost equal to the bandgap energy. Therefore, the wavelength of the emitted light can be selected by an appropriate choice of the semiconductor materials. Especially by using compound semiconductors, the wavelength of the LED can be tuned in a wide range, for instance, from orange to near-infrared through red wavelengths by $Al_xGa_{1-x}As$ or $GaAs_{1-x}P_x$ materials with various mole fraction x . Very recently, green or blue LEDs were achieved by GaN-related materials. As a result, semiconductor LEDs can realize full color display devices.

Laser Diodes

In LEDs, the light is emitted through a spontaneous recombination process of the electron–hole pairs. On the other hand, the electron–hole recombination is stimulated if there exists a light whose photon energy is same as the recombination energy. This stimulated recombination process plays an important role in lasers. Since the basic structure of the semiconductor laser is almost same as that of the LED, semiconductor lasers are often called laser diodes (LDs). The difference between LDs and LEDs is that the LDs have a cavity for lasing as shown in Figure 17. In the cavity, the light travels back and forth and is amplified by the stimulated emission. It is assumed that an incident plane wave to the cavity is $E_{in} = E_0 e^{j(\omega t - kx)}$, reflectances for input and output mirrors are R_1 and R_2 , transmittances for the input and output mirrors are $T_1 (=1-R_1)$ and $T_2 (=1-R_2)$, respectively, and a parameter representing a change in both amplitude and phase for one way in the cavity is γ . Then the total output E_{out} is given by

$$\begin{aligned} E_{out} &= E_{in} T_1 T_2 e^{-\gamma L} + E_{in} T_1 T_2 R_1 R_2 e^{-3\gamma L} + E_{in} T_1 T_2 R_1^2 R_2^2 e^{-5\gamma L} + \dots \\ &= E_{in} T_1 T_2 e^{-\gamma L} (1 + R_1 R_2 e^{-2\gamma L} + R_1^2 R_2^2 e^{-4\gamma L} + \dots) \\ &= E_{in} T_1 T_2 e^{-\gamma L} \frac{1}{1 - R_1 R_2 e^{-2\gamma L}} \end{aligned}$$

If $1 - R_1 R_2 e^{-2\gamma L} = 0$ is satisfied, a finite output is obtained even when $E_{in} = 0$, and this is the oscillation condition for lasers. Now, γ can be rewritten as $\gamma = i2\pi\bar{n}/\lambda_0 + (\alpha_{in} - g)/2$ where λ_0 , $\bar{n}$, α_{in} , and g are the wavelength in vacuum, the refractive index, the cavity internal loss, and the optical gain in the cavity, respectively. Therefore, one can introduce the following equations from the amplitude and phase condition for lasing:

$$R_1 R_2 \exp[(g - \alpha_{in})L] = 1 - 2i(2\pi\bar{n}/\lambda_0)L = i2m\pi \quad (m = 1, 2, 3, \dots)$$

Figure 16 Electron and hole injections through n -type and p -type regions, respectively, in the LED. The emitted photon energy is almost equal to the bandgap energy.

Figure 17 (a) A schematic of the LD where a laser cavity is added to the LED structure to achieve the laser oscillation, and (b) a model of light traveling in the laser cavity.

From the former equation, the threshold gain for lasing is given as $g = \alpha_{in} + (1/L)\ln R_1 R_2$, and the longitudinal mode of lasing light wavelength is given as $\lambda = 2L/m$ from the latter one. Consequently, if the amplifying gain owing to the carrier injection from outside is high enough to exceed the cavity losses (summation of internal loss and mirror loss), a laser emission occurs, that is, some threshold current is needed to achieve the laser emission. Above the threshold, the laser output power strongly increases as an increase of the injected current, as schematically illustrated in Figure 18. Since, on the other hand, the lasing wavelength is determined by the cavity length, the emitted light from the LDs is very coherent, very monochromatic, and highly directional, similar to other lasers such as solid-state lasers and gas lasers. The greatest advantage in LDs is their compactness in size. In order to

Figure 18 Typical current–light characteristics in the LD.

Figure 19 A double heterostructure to confine the carriers in the active region efficiently.

confine the carriers in the active region where a stimulated recombination occurs, double heterostructures are widely used as shown in Figure 19. The active region, in which the bandgap is tuned to be a desirable photon energy, is sandwiched by the barrier regions which have wider bandgaps than the active region and are oppositely doped to inject electrons and holes separately. Such active and barrier regions also act as core and clad regions for a waveguide structure, respectively, owing to the difference in refractive index. As a result, the traveling light wave and the injected carriers are effectively confined in the active region, which contributes to the high emission efficiency in the LDs.

When electrons are confined in very fine quantum well (QW) heterostructures, a 2DEG is formed similar to the HEMT device. As illustrated in Figure 20, the electron density of states in the 2DEG system looks like a staircase, so the electron distribution in the 2DEG is more concentrated near the band edge than that in the three-dimensional free electron system, which well raises the current–light conversion efficiency in the QW. As a result, many improvements in the laser characteristics, such as low threshold current, high modulation frequency, and narrow spectrum line width, are realized. In addition, by adopting lower-dimensional electron systems in quantum wires (QWI) and quantum dots (QD), more improvements are expected owing to their sharper density of states, as illustrated in Figure 20.

Wide Bandgap Materials

For semiconductor devices such as Si, Ge, GaAs, InP and their compounds have widely been used since the invention of the bipolar transistor. Their bandgaps are 1–2 eV, resulting in most of the applications for optic devices being limited in the yellow, red, and

Figure 20 Schematics of the electron density of states in (a) two-dimensional, (b) one-dimensional, and (c) zero-dimensional electron gas systems in the QW, QWI, and the QD, respectively.

infrared regions. However, according to the recent progress in crystal growth, it has been possible to fabricate the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ materials that have a wide bandgap, over 3 eV. By using them, green or blue light emission is realized. In addition, wide-gap materials have high voltage tolerance compared with the narrow-gap materials such that high electric fields can be applied to accelerate electrons, which brings about a possibility for very high-speed operations. Therefore, $\text{Al}_x\text{Ga}_{1-x}\text{N}$ materials are very hopeful for electronic devices as well.

Nomenclature

a_0	lattice constant (nm)
c	vacuum speed of light (cm s^{-1})
d	thickness of active region (μm)
D	diameter of circular active region in VCSEL (μm)
e	elementary charge (As)
E_c	conduction band edge energy (eV)
E_{Fc}	quasi-Fermi level in conduction band (eV)
E_{Fv}	quasi-Fermi level in valence band (eV)
E_g	bandgap energy (eV)
E_v	valence band edge energy (eV)
f	frequency (Hz)
g	optical material gain (cm^{-1})
h	Planck's constant (VAs ²)
H	modulation response
I	current (mA)
I_{th}	laser threshold current (mA)
k	wave vector (cm^{-1})
k_0	free-space wave vector $k_0=2\pi/\lambda$ (cm^{-1})
k_B	wave vector at Bragg wavelength (cm^{-1})
L	laser length (μm)
L_B	length of Bragg grating (μm)
$n=n'+jn''$	complex refractive index
n_{eff}	effective refractive index of a waveguide mode $n_{eff}=\beta/k_0$
n_g	group refractive index
n_{sp}	spontaneous emission coefficient (typically 1–2)
N	carrier density (cm^{-3})
N_c	effective density of states in conduction band (cm^{-3})
N_{th}	carrier density at laser threshold (cm^{-3})
N_v	effective density of states in valence band (cm^{-3})
P	optical power (mW)
R	recombination rate ($\text{cm}^{-3} \text{s}^{-1}$), mirror reflectivity (dimensionless)
RIN	relative intensity noise (dB Hz^{-1})
S	photon density (cm^{-3})
$SMSR$	side-mode suppression ratio (dB)
V_a	active region volume (cm^3)
v_g	group velocity (cm s^{-1})

w	stripe width (μm)
W	full width at half maximum (FWHM) (μm) of laser near-field
α	optical loss coefficient (cm^{-1})
α_{H}	Henry's line width enhancement factor
α_{i}	intrinsic optical loss (cm^{-1})
α_{m}	mirror loss (cm^{-1})
α_{tot}	total optical loss $\alpha_{\text{tot}} = \alpha_{\text{i}} + \alpha_{\text{m}}$ (cm^{-1})
β	propagation constant (cm^{-1})
Γ	confinement factor of an optical mode
ΔE_{F}	difference of quasi-Fermi levels, $E_{\text{Fc}} - E_{\text{Fv}}$ (eV)
$\Delta\Phi$	FWHM of laser far-field (rad°)
κ	coupling coefficient of Bragg grating (cm^{-1})
Λ	(Bragg) grating period (nm)
λ	wavelength (μm)
λ_{B}	Bragg wavelength (μm)
ν	frequency (Hz)
τ_{d}	differential carrier lifetime (s)
τ_{on}	turn-on delay time (s)
τ_{s}	photon lifetime (s)
ω	circular frequency (s^{-1})
ω_{d}	damping circular frequency (s^{-1})
ω_{r}	relaxation circular frequency (s^{-1})

Introduction

Even though more than four decades have passed since the first demonstration of lasing in semiconductors, the pace of development of new and further improved semiconductor lasers continues to be rather high. Judging by their economic impact, semiconductor lasers can be considered today as the most important type of laser. From the beginning, the development of semiconductor lasers has been closely connected with the progress of semiconductor technology and device physics. Hence, the invention of semiconductor heterostructures as well as the straightforward implementation of quantum effects together with improved epitaxial techniques have had a decisive impact on the evolution of these lasers. Besides the physical background and the various device concepts, a proper treatment of semiconductor lasers has to particularly include a description of the relevant materials and their fabrication technology.

After a brief review of the conditions for laser action in semiconductors, this article gives an overview of the most relevant semiconductor materials and material systems. Besides the materials, it is also shown that the various choices among the various laser structures makes this laser class well suited for a vast number of applications. The stationary, dynamic, and spectral characteristics of state-of-the-art semiconductor lasers are presented in the next section and a brief discussion on single-frequency and vertical-cavity surface-emitting semiconductor lasers completes this article.

Population Inversion and Gain in Semiconductors

A fundamental concept in laser physics is to achieve population inversion between two discrete states in a nonequilibrium physical system, so that the stimulated emission can overcome absorption and losses yielding a net optical gain. In a semiconductor, however, the energy states for electrons and holes are continuously distributed within energy bands that are separated by forbidden bands as schematically shown in Figure 1 for a direct semiconductor, where the width of the forbidden band is denoted as bandgap energy E_{g} . The population of these bands is governed by the Fermi distribution characterized by the Fermi level at which the population probability equals 0.5. A population inversion can be achieved by heavily pumping the semiconductor via a current injection. As shown in Figure 1, the nonequilibrium electron and hole distributions can be described by two equilibrium Fermi distributions with two Fermi levels E_{Fc} and E_{Fv} for the conduction and valence bands, respectively. This is possible due to the fast relaxation of the carriers within the bands, hence, E_{Fc} and E_{Fv} are named quasi-Fermi levels. In 1961, Bernard and Durauffourg derived the condition for population inversion in semiconductors essentially stating that the energy difference $\Delta E_{\text{F}} = E_{\text{Fc}} - E_{\text{Fv}}$ needs to exceed the bandgap energy, and the photon energy $\hbar\omega$ is between ΔE_{F} and E_{g} :

$$\Delta E_{\text{F}} > \hbar\omega \geq E_{\text{g}}$$

The Bernard and Durauffourg condition requires that the population of at least one band is degenerate, that is, the carrier density exceeds the effective density of states N_{c} and N_{v} of the conduction and/or the valence band, respectively. This means that the semiconductors are operated in the high-injection regime, since N_{c} and N_{v} are rather large. In GaAs, for instance, at room temperature, $N_{\text{c}} \cong 4 \times 10^{17} \text{ cm}^{-3}$ and $N_{\text{v}} \cong 8 \times 10^{18} \text{ cm}^{-3}$. Normally, undoped active regions are applied, so that the electron and hole densities are equal causing the conduction band to become degenerate. While, in principle, population inversion is

Figure 1 Schematic diagram of energy bands and quasi-Fermi levels of an inverted semiconductor illustrating the Bernard and Durauffourg condition.

possible in direct and indirect semiconductors, a sufficient gain to overcome internal absorption losses can hardly be achieved in indirect semiconductors.

For injection levels exceeding the threshold as defined by the Bernard and Durauffourg condition, an optical gain due to stimulated emission by the inverted band occupation occurs. The injection level at which this gain exactly compensates the material losses, such as free-carrier absorption or scattering losses, is defined as the transparency threshold. At even higher injection, the increasing gain may also compensate the mirror losses of an optical cavity enabling laser operation. It should be noted that inverted semiconductors may provide very large optical gain g up to the order of 1000 cm^{-1} , exceeding that of any other optical gain medium.

Semiconductor Heterostructures

Laser operation in homojunction semiconductors is difficult to achieve because of the high current densities required to achieve optical gain. For low-threshold operation, it is therefore necessary to reduce the volume of the active region in which the injection occurs and to exclude optical absorption in the surrounding semiconductor regions. This goal can most effectively be achieved by applying semiconductor heterostructures, in which semiconductors with different bandgap energy are combined. The most effective among them is the so-called “double heterostructure,” in which the active region is completely embedded into p - and n -doped semiconductors with a larger bandgap energy as shown schematically in Figure 2. The double heterostructure provides two essential features relevant for laser operation:

Figure 2 Schematic illustration of (a) semiconductor double heterostructure, (b) spatial profiles of bandgap energy, and (c) refractive index.

1. *Carrier confinement.* This almost completely concentrates electrons and holes within the active region even for active regions having thickness in the nm-regime.
2. *Optical confinement.* This yields optical waveguiding, establishing a slab waveguide with the active region as core because of the smaller refractive indices of the higher bandgap energy semiconductors sandwiching the active region.

Compared to the carrier confinement, the optical confinement as measured by the optical confinement factor

$$\Gamma = \frac{\text{mode power carried in active layer (region)}}{\text{total mode power}}$$

is not as complete for small dimensions, and the optimal radiation-matter interaction in the active region occurs where Γ/d is maximal. Depending on the material constants, accordingly, active region thicknesses are usually ~ 100 nm.

Further, an improved optical gain performance shows the quantum-well (QW) structures, in which the active region thickness is reduced to below the de Broglie wavelength (~ 30 nm). In QWs, the quantization of the electronic states along the normal layer results in a two-dimensional (2D) electron (and hole) gas with a modified density of states that makes the inversion population possible for smaller injection levels. The density of states in the valence band can additionally be modified by introducing elastic strain that lifts the degeneracy of light and heavy valence bands, so that only one of the two valence bands needs to be inverted yielding still smaller thresholds. Extending the quantization to the other two dimensions, one obtains quantum wire and quantum dot structures, corresponding to one-dimensional (1D) and zero-dimensional (0D) electron (hole) systems with distinct threshold reduction. In case of the quantum dot, atom-like discrete states appear to make this kind of gain medium rather similar to atomic laser media. In general, reducing the dimensionality of the carrier systems results in reduced thresholds and smaller temperature dependence of the optical gain. Because of the significant advantages achieved with double heterostructures, all modern laser diodes normally comprise a QW double heterostructure.

Semiconductor Heterostructure Material Systems

The benefits of the semiconductor heterostructure can be exploited only if the composite crystal exhibits a high crystalline quality. This generally requires that all constituents of the heterostructure have the same lattice constant a_0 , while the difference in bandgap energy should be large (several hundred meV). The lattice-matching requirement strongly limits the possible semiconductor combinations because semiconductor heterostructures are almost entirely grown on binary substrates. This is because binary substrates, such as GaAs or InP, are unambiguous chemical compounds in contrast to, for example, $\text{In}_x\text{Ga}_{1-x}\text{As}$ and typically provide more than an order of magnitude of better thermal conductivity than ternary (or quaternary) compounds because of the nonoccurrence of alloy scattering of the phonons.

Lattice-matched double heterostructures, therefore, consist of ternary and quaternary (or even quinary) compounds grown on binary substrates. The lattice-matching condition can be found from Vegard's law which states that the lattice constant of a compound can be calculated as a linear interpolation between the constituting binaries. For a quaternary compound $\text{A}_x\text{B}_{1-x}\text{C}_y\text{D}_{1-y}$, where A and B, and C and D each share the same sublattice, the lattice constant is

$$a_0(\text{A}_x\text{B}_{1-x}\text{C}_y\text{D}_{1-y}) = xy a_0(\text{AC}) + x(1-y) a_0(\text{AD}) + (1-x)y a_0(\text{BC}) + (1-x)(1-y) a_0(\text{BD})$$

On the other hand, the bandgap energy of a compound shows a more complicated and nonlinear dependence on composition. As a consequence, with a proper choice of semiconductor materials, rather large bandgap energy differences can be achieved with lattice-matched compounds making numerous heterostructure combinations possible. Semiconductor lasers are nowadays made from numerous III-V and other compound semiconductors covering the entire visible as well as the infrared regime up to ~ 100 μm wavelength.

Stripe Laser Diodes

A schematic drawing of the basic stripe-geometry semiconductor laser structures is depicted in Figure 3. All of them comprise a transverse (vertical, x -axis) double heterostructure to define the vertical extension of the laser-active area with a pn -junction at or in the active layer. A laser current is fed via stripe contacts on the top and bottom of the laser chips. Three basic types of lasers can be distinguished: gain-guided (GG), index-guided (IG), and quasi-index-guided (QIG) laser structures, where the guiding relates to the in-plane (lateral) waveguiding along the y -axis. While the transverse waveguiding (x -axis) is accomplished by index guiding via the double heterostructure, the lateral waveguiding may either be done (1) simply by the lateral gain profile in the active layer (GG), (2) similar to the transverse direction by a lateral double heterostructure (IG), or (3) by a partial lateral replacement of part of the structure by a lower index material without attaching the active layer (QIG). While the GG lasers require the lowest technological effort and generally show an excellent long-term stability because of the nonmodified active layer, the IG lasers exhibit the smallest thresholds and optimum laser performance; however, the lateral removal of part of the active layer may worsen the reliability. Often a reasonable compromise are the QIG lasers that, in all aspects, show the behavior in between the other two structures. An optical feedback is provided by the cleaved end-facets of the laser chips, which for typical refractive indices of the semiconductors (2.5–3.5)

Figure 3 The three different lateral waveguiding types (a) Gain-guiding (GG), (b) index-guiding (IG), and (c) quasi-index-guiding (QIG).

show a reflectivity $\sim 30\%$ against air. Due to the large gain of the semiconductor laser, this comparatively small mirror reflectivity can be compensated for by laser lengths of the order of several hundred micrometers.

Waveguiding in Laser Diodes, Effective Refractive Index, and Confinement Factor

The transverse double heterostructure represents an optical slab waveguide with the schematic index profile shown in Figure 2c. Depending on the active layer (core) thickness d and the index profile, this slab may carry one or more guided transverse electric (TE) and transverse magnetic (TM) modes, respectively. For a sufficiently thin active layer,

$$d < \frac{\lambda}{2\sqrt{n_2^2 - n_1^2}}$$

only the fundamental TE- and TM-modes are guided, which is normally aimed for.

The optical gain which the modes acquire, that is, the mode gain g_m , is the product of the active region material gain g and the optical confinement factor Γ for the particular mode. For a given slab waveguide, the (fundamental) TE-mode exhibits a larger confinement than the (fundamental) TM-mode. Also, the facet reflectivity shows a certain polarization dependence favoring the TE-modes as well. As a consequence, semiconductor lasers normally operate in the fundamental transverse TE-mode. In a good approximation, the confinement factor for the fundamental TE-mode is

$$\Gamma \cong \left[1 + \left(\frac{d_0}{d} \right)^2 \right]^{-1} \quad \text{with} \quad d_0 = \frac{\lambda}{2\pi} \sqrt{n_2^2 - n_1^2}$$

A further mode property is the effective refractive index n_{eff} , that describes the mode propagation along the waveguide in analogy with a plane wave in a homogeneous medium, with the refractive index equal to n_{eff} . The effective refractive index, which is the ratio of the propagation constant β and the free-space wave number k_0 , is between n_1 and n_2 .

Considering complex refractive indices $n = n' + jn''$, where the imaginary part is related to the material gain (or loss) g as $n'' = g/2k_0$, it is obvious that the gain in the active region leading to the mode gain produces a slightly complex propagation constant and a complex effective refractive index with imaginary part equal to $n'' = \Gamma g/2k_0$.

Besides transverse profiles of the real part of n , those of the imaginary part of n may also produce optical waveguiding. This explains why the lateral gain profile constitutes a waveguide for laser radiation in the GG lasers. For common gain values, however, the GG mechanism is much smaller than IG, with the consequence that the maximum stripe width w for lateral single-mode operation is much larger in the GG lasers than in their IG counterparts.

Output Power versus Current Characteristic

A representative plot of an optical output power versus current characteristic for a semiconductor laser is shown in Figure 4, together with the principal current-dependent carrier density in the active region. Relevant parameters of this characteristic are threshold current I_{th} , output power P , and differential quantum efficiency η_d . The threshold current is related to the active region volume V_a and the spontaneous recombination rate R at lasing threshold carrier density N_{th}

$$I_{\text{th}} = eV_a(N_{\text{th}})$$

where e is the elementary charge. The active region gain $g(N_{\text{th}})$ at injection level N_{th} yields a mode gain that equals the total losses α_{tot} comprising internal losses (e.g., absorption and scattering) α_i and the mirror losses α_m :

$$\Gamma g = \alpha_i + \alpha_m \quad \text{with the mirror losses}$$

$$\alpha_m = \frac{1}{2L} \ln \frac{1}{R_1 R_2}$$

where L is the laser length, and R_1 and R_2 are the front facet mirror reflectivities. For a symmetric laser with $R_1 = R_2 = R$, the optical output power per facet (above threshold) is

$$P(I) = \frac{h\nu}{2e} \frac{\alpha_m}{\alpha_{\text{tot}}} (I - I_{\text{th}})$$

and the differential quantum efficiency reads

$$\eta_d = \frac{dP/h\nu}{dI/e} = \frac{\ln 1/R}{2\alpha_{\text{tot}}L}$$

Emission Spectrum and Beam Properties

With state-of-the-art semiconductor technology, it is possible for most emission wavelengths to fabricate narrow-stripe laser waveguides that carry only one transverse and one lateral mode each. Even though the length of semiconductor cavities (typically

Figure 4 Schematic profile of optical output power P and carrier density in active region N vs. current in a semiconductor laser.

0.1–1 mm) is orders of magnitude smaller than that of most other laser types, the length-(effective)-refractive-index-product is still of the order of several thousand wavelengths. Therefore, the longitudinal mode spacing

$$\Delta\lambda = \frac{\lambda^2}{2n_g L} (n_g : \text{group (effective) index})$$

is very small against the spectral width of the active region gain characteristic, which in terms of energy is of the order of the thermal energy ($k_B T$). As a consequence, the mode gains of the modes near the gain peak are only slightly different, so that the usual Fabry–Perot-type semiconductor lasers generally emit in many longitudinal modes. The purity of the spectrum can be described by the side-mode suppression ratio (SMSR) that measures the ratio of the dominant mode to the next strongest one. Given the mode gain difference Δg_m between the two strongest modes, the SMSR of a symmetric semiconductor laser ($R_1=R_2$), under stationary conditions, is proportional to the power in the dominant mode P according to

$$\text{SMSR} = \frac{2P\Delta g}{h\nu n_{sp} v_g \alpha_{\text{tot}} \alpha_m}$$

where n_{sp} is the spontaneous emission coefficient (typically 2), that is specific for semiconductor lasers taking into account the incomplete inversion of the bands, and v_g is the group velocity. Truly single-mode lasers, that is, single-frequency lasers, show an $\text{SMSR} > 30$ dB, that is, three orders of magnitude, requiring a Δg of 0.01 – 0.1 cm^{-1} , which generally cannot be accomplished solely by the spectrally dependent active region gain. Single-frequency laser diodes, therefore, need additional wavelength selective elements such as Bragg reflectors as shown below.

An important spectral parameter, particularly for single-frequency semiconductor lasers, is the spectral line width of the mode(s). As with other lasers, the line width is obtained by the Schawlow–Townes formula; however, due to the gain-phase coupling in semiconductor lasers, the Schawlow–Townes formula must be completed yielding the so-called “Schawlow–Townes–Henry line width formula”

$$\Delta\nu = \frac{h\nu_g^2 \alpha_{\text{tot}} \alpha_m n_{sp}}{8\pi P} (1 + \alpha_H^2)$$

where α_H is Henry’s line width enhancement factor describing the gain-phase coupling accompanying carrier density changes in the active region which has the form

$$\alpha_H = -2k_0 \frac{\partial n' / \partial N}{\partial g / \partial N}$$

The physical origin for nonzero α_H is the nonsymmetric gain versus wavelength characteristic of semiconductor gain media. While the gain-wavelength characteristics of most other laser materials are symmetric, the asymmetry in semiconductors yields nonvanishing changes of the refractive index at the gain maximum, that is, at the laser wavelength, during the occurrence of gain changes, for instance, during relaxation oscillations or after each spontaneous emission event into the lasing mode(s). It should be noted that α_H is significantly smaller for QW lasers, particularly for strained QW lasers, than for bulk lasers. In case of the recently developed quantum dot lasers, α_H approaches zero because of the almost completely symmetric atom-like gain-wavelength characteristic.

The radiation beam of normal laser-diodes is transversely single-mode and nearly diffraction limited. In this case, the near-field and far-field widths depend on each other as

$$\Delta\Phi = \arctan\left(\frac{2\lambda}{\pi W}\right)$$

where $\Delta\Phi$ and W are the full width at half maximum (FWHM) of the far-field and near-field angles, respectively. Because of the narrow stripe widths of transversely single-mode semiconductor lasers (typically 0.5 – $3 \mu\text{m}$ at 1 – $2 \mu\text{m}$ emission wavelength), the diffraction-limited far-field width is of the order of several tens of degrees, in contrast to most other laser types.

Dynamic Properties and Noise

The dynamic properties of laser diodes are relevant for their use as a direct current-modulated light source in high-speed data transmission applications. Thereby, the two limiting cases of a linear response at a small-signal modulation and a nonlinear response at a large-signal (generally pulse) modulation are of great interest.

Modulating the laser around average current I and average output power P per facet, respectively, the small-signal modulation response $H(\omega)$ can be described by the transfer function of a damped second-order low-pass filter

$$H(\omega) = \frac{1}{1 - (\omega/\omega_r)^2 + j(\omega/\omega_d)}$$

where the relaxation and damping circular frequencies ω_r and ω_d are given as

$$\omega_r = \frac{1}{\tau_s} \sqrt{\frac{2a\Gamma}{v_g \alpha_m \alpha_{\text{tot}} h\nu V_a}} P \quad \text{and} \quad \omega_d = \frac{\tau_s}{\gamma} \omega_r^2$$

respectively. Here, the linear gain parameter $a = \partial g / \partial N$ and the photon lifetime in the cavity $\tau_s = (v_g \alpha_{\text{tot}})^{-1}$ appear, and γ is

$$\gamma = \frac{aS}{\alpha_{\text{tot}}} + \frac{\tau_s}{\tau_d} + \frac{n_{\text{sp}}\Gamma}{V_a S}$$

with τ_d being the differential carrier lifetime in the active region determined by the total spontaneous emission rate and nonradiative recombination processes (typically several nanoseconds). S is the photon density in the active region corresponding to output power P

$$S = \frac{2\Gamma}{v_g \alpha_m h\nu V_a} P$$

With an increase in the laser current or output power, respectively, the relaxation frequency as well as the damping frequency increases. The absolute value of the modulation response versus frequency f is shown in Figure 5 for a typical 1.55 μm wavelength InGaAsP laser in comparison with an LED made from the same semiconductor material. It is usual to measure $|H(\omega)|$ in decibels, that is, $10 \log |H(\omega)|$. The characteristic 3-dB bandwidth is only slightly larger than the relaxation resonance, so that the latter can be used as a reasonable measure for the modulation bandwidth.

The large-signal pulse modulation can be described by rather accurate approximations for the turn-on delay τ_{on}

$$\tau_{\text{on}} \cong \tau_d \frac{I_{\text{on}} - I_{\text{off}}}{I_{\text{on}} - I_{\text{th}}} \quad \text{for } I_{\text{off}} < I_{\text{th}} < I_{\text{on}} : \text{off-state below threshold}$$

$$\tau_{\text{on}} \cong \frac{\sqrt{2}}{\omega_r} \ln \frac{P_{\text{on}}}{P_{\text{off}}} \quad \text{for } I_{\text{th}} < I_{\text{off}} < I_{\text{on}} : \text{off-state above threshold}$$

where switching occurs from $P_{\text{off}}(I_{\text{off}})$ to $P_{\text{on}}(I_{\text{on}})$. While for lasers biased below threshold, the τ_{on} delay is of the order of the comparatively long differential carrier lifetime τ_d , τ_{on} delays ~ 0.1 ns can be obtained with an above-threshold bias.

Besides the phase noise that determines the modal line width, an intensity noise occurs in semiconductor lasers. This is usually described in terms of the relative intensity noise (RIN)

$$\text{RIN (in dB Hz}^{-1}) = \frac{1}{\Delta f} \log \left(\frac{\Delta P}{P} \right)^2$$

where ΔP denotes the power fluctuations of the laser output within bandwidth Δf . The RIN shows a frequency dependence similar to the modulation response with typical low frequency values ~ 135 dB Hz $^{-1}$.

Single-Frequency Semiconductor Lasers

Semiconductor lasers can be made single-frequency lasers by introducing additional wavelength-selective elements into the laser cavity that select only one of the longitudinal modes. This is commonly accomplished with Bragg gratings monolithically integrated into the laser structure. As shown in Figure 6, the gratings may either replace the laser mirrors and are therefore put at one or both laser facets (distributed Bragg reflector (DBR) laser with a longitudinal integration of grating) or may homogeneously be collocated with the active region over the entire laser length (distributed feedback (DFB) laser with a transverse integration of grating). To avoid interference with the end facet reflection, antireflection coatings are normally applied onto those facets of DBR lasers where the gratings provide the feedback. In DFB lasers, therefore, both facets need an antireflection coating to suppress these interferences.

Figure 5 Absolute value $|H(f)|$ of the modulation response of a laser diode.

Figure 6 (a) DBR (longitudinal integration), and (b) DFB (transverse integration) single-frequency semiconductor laser structures.

The Bragg gratings are made by periodic thickness variations of a grating layer sandwiched between layers of different refractive indices, so that the thickness variations result in effective refractive index variations Δn_{eff} of the same periodicity. In the DBR laser, the Bragg grating introduces a wavelength-dependent mirror loss with a minimum loss or maximum reflectivity at the (free-space) Bragg wavelength

$$\lambda_B = 2n_{\text{eff}}\Lambda$$

where Λ is the grating period, (Figure 6b). In the interesting regime around the Bragg wavelength, the wavelength-dependent reflectivity can be calculated by the coupled-mode theory yielding

$$R(\lambda) = \left| \frac{\kappa \sinh(sL_B)}{j\Delta\beta \sinh(sL_B) + s \cosh(sL_B)} \right|^2$$

where κ , the coupling coefficient of the grating describing the strength of the grating feedback has the form

$$\kappa = \frac{k_0 \Delta n_{\text{eff}}}{4}$$

and $\Delta\beta$ is the deviation of the wave vector $k_0 n_{\text{eff}}$ from the wave vector at the Bragg wavelength k_B and is thus a measure of the difference $\Delta\lambda = \lambda - \lambda_B$

$$\Delta\beta = k_0 n_{\text{eff}} - k_B \cong -\frac{2\pi n_{\text{eff}}}{\lambda_B^2} \Delta\lambda$$

L_B is the grating length, and $s = \sqrt{\kappa^2 - \delta\beta^2}$. At the Bragg wavelength, the reflectivity is maximal and is given by

$$R(\lambda_B) = \tanh^2(\kappa L_B)$$

For most DBR semiconductor lasers, it is possible to achieve κL_B -products of the order 1 or more and thus to realize reasonable reflectivities exceeding even the facet reflectivity of the semiconductor–air interface in the Fabry–Perot semiconductor lasers. However, the relative spectral position of the Bragg wavelength and the longitudinal mode spectrum is not controlled well in DBR lasers, particularly, if a wide operation temperature range is considered with resulting relative shifts of both against each other. The wavelength control and stability is much better in the DFB lasers because the longitudinal DFB laser modes are intrinsically related to the Bragg wavelength, and the grating and the active region are spatially not separated, so that any index changes in the active region or the grating layer may not change this relationship. As a consequence, DFB lasers have become commercial single-frequency lasers, while more sophisticated DBR devices have gained importance in the area of wavelength-tunable semiconductor lasers. Properly designed DFB lasers show excellent single-frequency performance with SMSR well exceeding 30 dB.

Vertical-Cavity Surface-Emitting Semiconductor Lasers

Vertical-cavity surface-emitting lasers (VCSELs) are relatively new semiconductor lasers in which the laser cavity is not along the wafer plane but vertical to it. Consequently, the length of the gain region along which the optical gain compensates internal and mirror losses is drastically reduced to the thickness of the active region (e.g., 50 nm) instead of its length (e.g., 500 μm). Because of the large optical gains achievable with semiconductors, it is possible to realize a sufficient gain along a gain path length of only 5–50 nm for the compensation of the losses of high-reflective mirrors. A schematic illustration of the basic VCSEL geometry is shown in Figure 7. Top and bottom mirrors of the VCSEL consist of several ten quarter-wavelength semiconductor layer pairs with alternating refractive index that can precisely be fabricated with molecular beam epitaxy (MBE) or metal-organic vapor-phase epitaxy (MOVPE).

The cavity length of VCSELs is of the order of the wavelength and thus orders of magnitude shorter than that of the edge-emitting lasers. Accordingly, the laser performance shows substantial differences, such as a longitudinal single-mode operation or the onset of quantization effects of the optical field.

Using thin QW active layers, the thickness d of the active region can be made much thinner than a quarter wavelength in the semiconductor, that is, $\lambda/4n$, so that by placing the active region in a maximum of the field intensity $|E|^2$ as shown in Figure 7, the gain is twice as large for the long active regions in edge-emitting layers, where the gain works on the averaged field intensity, including nodes of $|E|^2$ as well. The threshold condition for this design, therefore, reads (note the factor of 2)

$$2dg = \alpha_i L_{\text{eff}} + \frac{1}{2} \ln \frac{1}{R_1 R_2}$$

where the effective cavity length L_{eff} is the vertical extension of the standing wave within the $1/e$ -decay on both ends. Due to the ultra-small d , the mirror reflectivities need to be near unity, typically >99%. This can be achieved by DBRs made of alternating (and conductive) semiconductor layers of different composition yielding different refractive indices. Mathematically, the peak reflectivity of such a DBR at the Bragg wavelength is expressed as

Figure 7 Schematical illustration of principal vertical-cavity surface-emitting laser (VCSEL) structure.

$$R = \left[\frac{1 - (n_0/n_2)(n_2/n_1)^{2N}}{1 + (n_0/n_2)(n_2/n_1)^{2N}} \right]^2$$

where N is the number of layer pairs in the DBR, n_0 and n_2 are the refractive indices of the medium outside the VCSEL (e.g., air: $n_0=1$) and the inner semiconductor region respectively, and n_1 is the refractive index of the second semiconductor in the DBR. With refractive index differences up to 5–10% in usual semiconductor material systems (GaAlAs/GaAs, InGaAlAs/InP), several ten-layer pairs give reflectivities of the order 99.5–99.9% against air. With these high reflectivities, the laser threshold can be achieved with reasonable active region gains $\sim 500\text{--}1000\text{ cm}^{-1}$. Up to now, room-temperature continuous-wave VCSELs have successfully been demonstrated for the wavelength ranges 850–1000 nm in Ga(In)AlAs/GaAs, 1.2–1.3 μm in GaInNAs/GaAs, and 1.3–2.0 μm in AlGaInAs/InP.

The lateral diameter of the active region can be kept small enough to favor single transverse-mode operations and is typically $\sim 3\text{--}10\text{ }\mu\text{m}$. As a consequence of the small active region volume, the threshold currents of VCSELs are rather small, typically $< 1\text{ mA}$, even though the threshold current density might be quite large to obtain the required large threshold gain. Another consequence of the small active region is that the output power of a VCSEL is accordingly small, typically of the order of a few milliwatts, which is, however, sufficient for the vast majority of applications in communications, measurements, and sensing.

Introduction

A transistor is a three-terminal device, where the voltage or current applied to one terminal controls the current flow between the other two terminals. Transistors are designed to have current or voltage gain, which means a drivability of multistep transistor circuits. Submicron lithography and self-alignment have been used to improve the high-frequency operation of transistors. Transistors are key devices in cutting-edge semiconductor integrated circuits.

There are mainly two types of transistors, bipolar and field effect transistors. Transistors have been made on many systems, mainly semiconductor systems, including Si, SiGe, and III–V semiconductors. Since this encyclopedia concerns condensed matter physics, the basic principles of transistor operation and the fundamental performance of transistors, with emphasis on III–V semiconductor transistors, are discussed. Although the basic principles can be applied to many different systems, detailed discussions of transistor structures, transistor materials, processing, and circuit designs are omitted due to space constraints. (See “Further reading” section for details.)

Transistors, that is, three-terminal control devices, are important not only for electrical applications but also for physics studies. Several transistor devices often used in the study of transport physics at low temperatures are also discussed in the second half of this article.

Bipolar and Hetero-Bipolar Transistors

The principal operation of the (hetero) bipolar transistor is schematically shown in Figure 1. Although a bipolar transistor with n -type emitter, p -type base, and n -type collector (n - p - n transistor) is assumed in this figure, similar parameters are applicable to a p - n - p transistor. In the bipolar transistor, the most important factor determining transistor operation is current gain, that is, the ratio between J_C and J_B , where J_C and J_B are collector current and base current, respectively. When this ratio becomes larger than unity, the transistor has a gain. The current injected from the emitter passes through the base and reaches the collector. When the diffusion constant of electrons in the p -type base is small or the base layer is thick, the probability of electron transmission to the collector decreases. Some amount of the base current also diffuses to the emitter. Calculating all these factors results in the current gain h_{fe} determined by the emitter injection efficiency:

$$h_{fe} = \frac{n_E}{p_B} \frac{v_e}{v_h} \frac{N_{CB}}{N_{CE}} \frac{N_{VB}}{N_{VE}} \exp\left(\frac{\Delta E_g}{KT}\right) \quad [1]$$

where n_E and p_B are, respectively, the emitter and base doping concentration, v_e (v_h) is electron (hole) effective velocity toward the collector (toward the emitter) at the collector-side (emitter-side) base edge, and N_{CB} and N_{CE} (N_{VB} and N_{VE}) are densities of states in the conduction (valence) band for base and emitter, respectively. $\Delta E_g = E_{ge} - E_{gb}$ is the bandgap difference between emitter and base semiconductors.

For a thick emitter, v_h is determined by $v_h = D_h/L_E$, where D_h is the hole diffusivity in the emitter region and $L_E = \sqrt{D_h \tau_E}$ is the diffusion length. τ_E is the recombination lifetime in the emitter region. In the case of the thin base with $W_B < L_B$, v_e is represented as

$$v_e = D_n / (L_B \sinh(W_B/L_B)) = D_n / W_B$$

where D_n , L_B , and W_B are the electron diffusivity in the base region, electron diffusion length in the base, and the base thickness, respectively. In this situation,

$$h_{fe} = \frac{n_E}{p_B} \frac{L_E}{W_B} \frac{D_n}{D_h} \frac{N_{CB}}{N_{CE}} \frac{N_{VB}}{N_{VE}} \exp\left(\frac{\Delta E_g}{kT}\right) \quad [2]$$

Figure 1 Schematic band diagram of an HBT with graded emitter-base junction. The schematic current flow, which determines the transistor operation, is also shown.

In the case of a homojunction bipolar transistor, such as an Si bipolar transistor, $\Delta E_g = 0$, and h_{fe} is mainly determined by $n_E/p_B/W_B$. In order to maintain a suitable high value of h_{fe} , $n_E/p_B \sim 100\text{--}1000$ is typically chosen. The hole density of the base, p_B , usually becomes $10^{17}\text{--}10^{18}\text{ cm}^{-3}$ for the emitter electron density, n_E , of $10^{20}\text{--}10^{21}\text{ cm}^{-3}$. The current gain also increases with decreasing base layer thickness. However, the base resistance increases with decreasing p_B and W_B , so that there is a limitation to how far these parameters can be decreased in actual transistors. Si bipolar transistors are widely used in high-speed semiconductor circuits, owing to the many improvements in techniques for forming the emitter and base junctions, in isolation methods, and in the degree of self-alignment between the different device regions. Silicon is an indirect bandgap semiconductor and has a long recombination lifetime, so that the situation $W_B < L_B$ and a low-base resistance can be achieved even for a small p_B . However, direct bandgap semiconductors, such as GaAs, have a short recombination time, and the high n_E/p_B ratio necessary for the high-current gain is not possible. Therefore, it is difficult to build high-performance homojunction bipolar transistors from III-V semiconductors.

When heterojunctions are used, $\exp(\Delta E_g/kT)$ makes the most important contribution to h_{fe} . Improved transistor performance is expected by combining silicon-based transistors and Si/SiGe heterojunction systems. Furthermore, the large bandgap difference in III-V semiconductors enables one to use direct bandgap semiconductors in heterobipolar transistors (HBTs). This is because the term $\exp(\Delta E_g/kT)$ sufficiently compensates for the small n_E/p_B , and a thin base layer with high-carrier density becomes available. HBTs using many kinds of III-V semiconductor materials have been demonstrated.

At an abrupt heterojunction between different semiconductors, there is a discontinuity in the energy of the conduction-band minima and valence-band maxima. An energy barrier in the conduction band at the emitter-base junction tends to retard the flow of electrons from the emitter to the base. To avoid the barrier in the conduction band, a graded-alloy composition at the emitter-base junction has been used as shown in Figure 1. However, it is noteworthy that the barrier at the emitter-base junction is advantageous for high-speed operation because of the higher-energy electron injection from the emitter to the base. Therefore, an optimal design of the graded junction is necessary in actual HBTs.

For HBTs, many kinds of heterostructures have been studied. Figure 2 shows a comparison of the breakdown electric field of HBTs composed of Si/SiGe, InGaP/GaAs, InP/InGaAs, and GaN/InGaN material systems. The breakdown electric field of nitride-based HBTs is much higher than those reported for HBTs composed of other material systems. Therefore, GaN-based HBTs have recently received much attention as candidates for high-power and high-speed devices in the future. Here, the typical structures and characteristics of HBTs are discussed using GaN-based HBTs as examples. Figure 3 illustrates the schematic structure of the GaN/InGaN HBTs. In this peculiar device, the graded region is formed between the base and collector to reduce electron

Figure 2 Comparison of breakdown electric field of HBTs composed of various material systems.

Figure 3 GaN/InGaN HBT structure with a regrown p -InGaN extrinsic base layer.

scattering at the collector barrier, because the same bandgap material (GaN) is used for both the emitter and collector. A regrowth InGaN base contact is adopted to decrease the series resistance of the base. Actually, how to make a good contact to a thin base layer is a very important issue for HBTs with a thin base layer, and efforts to resolve this issue are underway for many heterostructure HBTs. The common emitter current–voltage characteristics of GaN/InGaN HBT with a $50\text{ }\mu\text{m} \times 30\text{ }\mu\text{m}$ emitter area are shown in Figure 4. The maximum collector gain exceeds 2000 in this device. Although this current gain is still less than the maximum gain of 5000 for Si/SiGe systems and 50000 for InP-based systems, the current gain for GaN-based systems has increased almost two orders of magnitude from the year 2000.

Field Effect Transistors: MISFET, MESFET, and HEMT

Bipolar transistors use both majority and minority carriers in semiconductors. There is, however, another type of transistor, where only the majority carriers are used and their density is controlled by an electric field effect. This type of transistor is called a field effect transistor (FET) and is widely used in many semiconductor systems. Several types of FETs are schematically shown in Figure 5. Metal–insulator–controlled semiconductor FETs (MISFETs) are shown in Figure 5a. When a positive bias is applied to the gate, conductive electrons start accumulating at the semiconductor–insulator interface. Due to the confinement by the electric field, the accumulated electrons have a two-dimensional (2D) nature. The threshold voltage, V_{th} , where electrons start accumulating, is determined by the semiconductor properties and interface characteristics. The density of accumulated charge, Q , is proportional to the gate bias and is represented as

Figure 4 Common-emitter current–voltage characteristics of a GaN/InGaN HBT at room temperature. Base current is $5\text{ }\mu\text{A/step}$.

Figure 5 Schematic diagrams of field effect transistors (FETs). (a) MISFET (MOSFET), (b) MESFET, and (c) HEMT (MODFET).

$$Q = ne = C_g(V_g - V_{th}) \quad [3]$$

where n , e , and C_g are the area density of electrons, electron charge, and capacitance of the gate insulator, respectively. When the bias is applied between the source and drain (V_d), the drain current (I_d) is determined by the carrier density (n) and the mobility of the carrier (μ). In the case of small V_d , where carrier density is constant over the whole device,

$$I_d = \frac{Z}{L} \mu ne V_d \quad [4]$$

where Z and L are the channel width and length of the MISFET. In the case of the MISFET, ne is expressed by eqn [3], then

$$I_d = \frac{Z}{L} \mu C_g (V_g - V_{th}) V_d \quad [5]$$

With increasing V_d , the carrier density near the drain edge decreases and finally becomes zero (pinch-off) at around $V_d = V_g - V_{th}$. Further increasing V_d results in an almost constant drain current independent of V_d , because a balance is achieved between the pinch-off of the carrier and the high electric field concentrating in the pinch-off region. Therefore, $I_d V_d$ characteristics of MISFETs, schematically shown in Figure 6, are separated into linear and saturated regions. The drain current in the saturated region, I_{ds} , is approximately expressed as

$$I_{ds} = \alpha \frac{Z}{L} \mu C_g (V_g - V_{th})^2 \quad [6]$$

where α is a constant close to unity.

In the case of Si, silicon dioxide (SiO_2) is used as the gate insulator. Therefore, the FET is normally called metal-oxide-semiconductor FETs (MOSFETs). It is also possible to accumulate conductive holes by applying negative bias to the gate. Combining n -type (electron transport) MOSFETs and p -type (hole transport) MOSFETs results in complementary MOSFET devices (CMOS devices). The Si MOSFET and CMOS devices are the most important devices in the very large scale integrated circuits used in microprocessors and semiconductor memories.

In MISFET devices, some other combinations of insulators and semiconductor materials are also possible. A good example is the InP MISFET, where electrons can accumulate at the interface between the InP and insulator, such as Al_2O_3 . However, the conductive carriers cannot be accumulated at the interface when the density of states of the interface defects is very large, as is the case at insulator-GaAs interface.

To avoid a direct and uncontrollable leakage current between the drain and source, n -type (p -type) MISFETs are fabricated on p -type (n -type) or semi-insulating materials. For the purpose of distinguishing these two types of MISFETs, the former is called an inversion-type MISFET and the latter an accumulation-type MISFET. For both types, the gate-induced carriers need to contact the

Figure 6 Schematic drain current-drain bias characteristics of a MISFET (MOSFET). Actual value of the drain current depends on device parameters and carrier mobility.

source- and drain-conductive regions (doped regions) so that an overlap between source- (drain-) conductive regions and gate is essential for the FET operation. The self-alignment process allows one to make such an overlap without increasing the capacitance between the gate and source (drain).

Another type of FET is the metal–semiconductor FET (MESFET). Figure 5b is a schematic diagram of a MESFET. In this device, conductive carriers are supplied from the 3D doping layer, and the number of conductive carriers is controlled by a depletion region spreading from the Schottky metal gate. The conductive layer thickness is determined by subtracting the depletion region thickness (W_d) from the total thickness of the doping layer. For the n -type conducting channel,

$$W_d = \sqrt{\frac{2\epsilon(V_{bi} - V_g)}{eN_d}} \quad [7]$$

where V_{bi} , ϵ , and, N_d are the built-in potential of the Schottky gate, dielectric constant of semiconductor, and donor density of the doping layer, respectively. The area density of the conductive carrier can be easily estimated from the conductive layer thickness, and the drain current is determined by eqn [4] in small V_d regions. Forming the conductive layer involves several techniques, such as ion-implantation and epitaxial growth.

Finally, there is the high-electron-mobility transistor (HEMT) which is shown in Figure 5c. The HEMT utilizes conductive carriers accumulated at the hetero-interface between wide- and narrow-gap semiconductors. A triangular-shaped confinement potential at the interface defines the conductive carrier in a thin 2D channel. Modulation doping, that is, doping in the wide-gap semiconductor and conductive carriers at the interface, enables one to separate conductive carriers from dopant impurities, which results in a strong suppression of impurity scattering. Therefore, HEMTs are also called modulation-doped FETs (MODFETs). The density of the 2D electron system is controlled by the gate bias and the $I_d V_d$ characteristics are roughly represented by eqns [3]–[6]. The most widely studied HEMT devices are based on the AlGaAs/GaAs system; however, many different material combinations, such as InAlAs/InGaAs and AlGaN/GaN systems, have been developed recently.

High-frequency FETs are key devices in recent optical communications technology, where they enable the practical use of 40 Gbit s^{−1}. Figure 7 summarizes current gain cut-off frequencies (f_T 's) for various kinds of FETs. Among them, InP-based HEMTs, where a conductive two-dimensional electron gas (2DEG) channel is formed in the InAlAs/InGaAs heterostructures lattice-matched with InP substrate, have achieved record f_T 's for a wide range of gate lengths (L_g 's) by many research groups. The effective saturation velocity of InAlAs/InGaAs HEMTs is 2.7×10^7 cm s^{−1}, ~ 1.3 times higher than that of GaAs-based HEMTs. Moreover, higher electron mobility and sheet-carrier density of the 2DEG at the InAlAs/InGaAs hetero-interface reduce channel and parasitic charging times, and make possible the effective use of higher saturation velocity. The current record f_T for a discrete device is beyond 400 GHz.

Integrated circuits (ICs) based on InP have been developed with the aim of achieving a 100 Gbit s^{−1} class communications technology. The schematic structure of such an IC is shown in Figure 8. A 0.1 μ m-gate InAlAs/InGaAs HEMT is integrated with

Figure 7 Current gain cut-off frequencies for various kinds of FETs.

Figure 8 Schematic diagram of an InP-based HEMT IC.

InAlAs Schottky diodes, metal resistors, and metal-insulator-metal (MIM) capacitors in this example. The mushroom-shaped gate improves transistor performance.

Modulation-doped HEMT structures are important not only as cutting-edge room-temperature devices but also as key devices for studies of low-temperature physics. The 2D electron system at the AlGaAs/GaAs interface has the highest mobility at low temperatures, and has been very important in quantum Hall effect research. Mobility up to $10^7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ has been obtained in

several laboratories in the USA, Europe, and Japan. The mobility is still limited by background impurities; therefore, it can be improved by increasing electron density. Recently, Bell Laboratories used a sophisticated MBE technique and two-side modulation-doping, and achieved mobility of around $3 \times 10^7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$.

Backgated Structures

The backgated structure, where carrier density is modulated from the back side by a voltage applied to the backgate, is also attractive. Although the gate capacitance limits high-frequency applications, the density control from the back side enables one to use the free surface for many kinds of structures. When fine structures are formed on the surface side, the structure behaves as a density-tunable mesoscopic system.

An example of a backgated heterostructure is shown in Figure 9. In this example, the 2D electron system accumulates at the hetero-interface between AlGaAs and GaAs. Conductive electrons are supplied from the ohmic contacts as in Si MOSFETs. The threshold voltage of the 2D electron accumulation is determined by the balance between surface charge and backgate bias. In case of the GaAs, the surface charge is frozen at low temperatures and the surface Fermi level is not pinned at the midgap. These features help in accumulating 2D electron systems with a small threshold voltage at low temperatures. Once the 2D electron system is accumulated at the hetero-interface, its density can be precisely controlled by the backgate bias, that is, an electric field applied between the 2D electrons and the backgate.

In-Plane-Gate Transistor

Transistors, that is, three-terminal devices, have been applied to confine electron systems to low dimensions, such as one and zero dimensions. When a pair of split Schottky gates is formed on a semiconductor heterostructure, such as AlGaAs/GaAs, the 2D electron system under the gates is depleted by a negative gate bias applied to the Schottky gates (see Figure 10a). The small distance between the two gates results in a narrow electron channel, which shows clear 1D features at low temperatures. Quantized conductance characteristics have been observed for such narrow and ballistic 1D channels, which are called quantum point contacts.

A unique transistor structure, called the in-plane-gate transistor, is formed by separating a 2D electron system into three parts using insulated lines as shown in Figure 10b. These insulating lines are made by trench etching or ion implantation. When a negative bias is applied to two side gates against the center region, the depletion region spreads from the insulating lines and a 1D channel is formed in the center channel. As shown in Figure 10c, quantized conductance characteristics have been reported, reflecting the successful formation of such a channel. Although the in-plane-gate FET is limited to a 1D system from the operation principle, three-terminal structures are made without Schottky gates. Therefore, the in-plane-gate FET is beneficial for many narrow-gap semiconductors, where the formation of a good Schottky gate is difficult.

Figure 9 Example of a backgated heterostructure.

Figure 10 Quantum point contacts (QPCs) fabricated by the FET technique. (a) Split Schottky gate QPC, (b) in-plane-gate QPC, and (c) typical characteristics of an in-plane-gate QPC fabricated on InSb quantum-well structure.

Single-Electron Transistor

In FETs, the number of carriers in the channel is determined by the gate bias through capacitance coupling. By combining FETs and nanotechnologies, it becomes possible to realize the structure schematically shown in Figure 11a. There is a small channel, like a quantum dot, which is separated from the source and drain by two barriers. The barrier height is set high enough to protect normal current flow, but low enough to permit tunneling coupling between the quantum dot and source (drain). The charge in the quantum dot increases linearly with the gate bias as represented by $Q = C_g V_g + Q_0$, where Q is the charge in the quantum dot, C_g gate

Figure 11 (a) Schematic diagram and (b) schematic operation principle of an SET. The position of the conductive peak is extremely sensitive to the charge balance in the circumstances schematically shown by the dotted lines.

capacitance, V_g gate bias, and Q_0 the background charge determined by the balance of the quantum dot in the system. When electrons accumulate in the quantum dot, Q should be an integer multiple of e , the charge of a single electron. This discrete nature of the charge is not important for a large system, but becomes essential for a small system such as the quantum dot, where $\Delta V_g = e/C_g$ becomes larger than the thermal broadening, kT/e . This situation is fully satisfied for the small quantum-dot system at low temperatures, and such three-terminal structures are called single-electron transistors (SETs).

A schematic diagram of an SET operation is shown in Figure 11. According to the increase in the gate bias, the charge in the quantum dot increases along a step function Ne (N : integer). A current flow, that is, electron flow, should be accompanied by a change of the number of electrons in the quantum dot. Therefore, the current flow is limited only in the condition where N can change with $\Delta N = 1$. On the other hand, the current flow is blocked when N is constant (Coulomb blockade).

Some SET characteristics are shown in Figure 12. The quantum dot has a circular disk shape in this example. The interval of current peaks determined by $\Delta V_g = e/C_g$ decreases with increasing bias. This is because an increase in the disk size with gate bias results in increased gate capacitance. In addition to the classical charging effect, quantum effects, such as the formation of zero-dimensional energy states, become important in small quantum dots. The zero-dimensional energy levels are represented by the diagram in Figure 12b for the parabolic confinement, which is a good approximation of the disk-shaped quantum dot. Here, $\hbar\omega_0$ represents the zero-dimensional energy-level separation arising from the parabolic confinement. The zero-dimensional energy levels degenerate at zero magnetic field, where $\omega_c = 0$. Each energy level can include two electrons with different spins. Therefore, ΔV_g increases for $N = 2, 6, 12, \dots$ where the zero-dimensional energy separation should be compensated by the gate bias in addition to e/C_g . Such periodic features have actually been observed as shown in Figure 12a for a circular quantum dot. This periodic feature comes from the same principle as the periodic table of real atoms, so that these SETs are sometimes called semiconductor artificial atoms.

At low temperatures, the conductive peak becomes sharp as experimentally shown in Figure 12a. Furthermore, the peak position shifts when the charge situation around the quantum dot is slightly modified as schematically shown in Figure 11b. Therefore, the conductance change in an SET operates as a very sensitive electrometer. Recently, the single electron motion in semiconductor nanostructures was detected by using the SET-based highly sensitive electrometer.

Figure 12 (a) Current vs. gate voltage characteristics experimentally observed for the disk-shaped SET. The current peak interval becomes wider for N (the number of electrons in the quantum dot) of 2, 6, 12, $\dots$, as shown by arrows. Such characteristics are explained by the zero-dimensional energy levels formed in the circular quantum dot and shown in (b). This energy diagram is calculated for a parabolic confinement potential, $V = m\omega_0^2(x^2 + y^2)/2$. $\hbar\omega_c$ is the cyclotron energy separation in the perpendicular magnetic field.

In 1781, Henry Cavendish discovered that water is not a primary chemical element, as had been believed for millennia, but a compound formed by the combination of hydrogen and oxygen. This discovery provided Antoine Laurent Lavoisier with insight concerning the true nature of the elements and stimulated him to undertake extensive experimental investigations in a search to identify as many elements as possible. His views were formalized in 1789 by the publication of a two-volume treatise (Figure 1) that provided the platform for the evolution of modern chemistry.

In his search for new elements, Lavoisier commonly attempted to reduce with hydrogen what were presumably compounds of the elements, a procedure that was particularly successful with the heavy metal oxides. In the course of this work, he decided that the mineral quartz was probably the oxide of an interesting element, but failed in his attempts to reduce it. A quarter of a century later, the distinguished Swedish chemist Joens Berzelius (Figure 2) finally achieved that goal. The newfound element ranked as an oddity. While it had some of the characteristics of a metal, such as a somewhat shiny metallic luster and the ability to conduct electricity, its conductivity was poor compared to that of silver and copper and decreased rather than increased as the temperature was lowered.

Since no immediate use was found for it, early samples of silicon were in the main assigned an honored place within exhibits of the chemical elements. However, the situation with respect to silicon changed radically during the last quarter of the nineteenth century, by which time professional chemists, well-trained in scientific methods, were in charge of research and development in fields such as metallurgy, ceramics, enamels, pigments, and dyes, replacing the ancient breed of investigators who had depended with some degree of success upon tradition, hunches, and mysticism. There was, for example, much interest at this time in the study of the magnetic properties of iron and its alloys that were being used in electric generators, motors, and transformers for many power-handling applications. Systematic research disclosed the existence of a family of iron–silicon alloys whose magnetic properties were much better than those of pure iron for many purposes. Moreover, relatively modest additions of silicon to some forms of steel could confer superior properties in matters such as toughness. In any event, silicon had finally become a very useful element in technical application and was beginning to be produced commercially at a level of ~98% purity.

During this same period, two other developments that were to influence the use of silicon in fields of technology occurred. First, a young German physicist, Dr. Ferdinand Braun (Figure 3), decided to extend prior research carried out earlier by Michael Faraday on the electrical properties of materials that were neither good insulators nor good electrical conductors. His target group included some ionic crystal, such as salts that permit ionic conductivity, and what are now called semiconductors, which were found eventually to conduct electronically. Both types of substance are distinguished by the fact that their electrical conductivity decreases toward zero at sufficiently low temperatures. Working with specimens of semiconductors, particularly with heavy metal sulfides, Braun discovered crystal rectification in 1874, that is, asymmetrical flow of current in a crystalline specimen for a given voltage when applied in opposite directions. In the course of his investigations, he demonstrated that it was a surface effect, Ohm's law connecting the current and field strength being valid in the bulk of the specimen.

The second significant development was Heinrich Hertz's production of electromagnetic radiation in the meter and shorter range of wavelength with hand-fabricated condensers, inductance, and antennae. This generated widespread interest in the possibility of long-range transmission and reception of such waves, a goal that was led in a very dynamic way by Guglielmo Marconi.

Initially, the propagation of an electromagnetic wave was detected by means of an ingenious device known as the coherer, invented in 1890 by the French physicist Edouard Branly. The coherer contained a bundle of metallic needles that aligned parallel to one another when an electromagnetic wave passed through the needles, thereby altering the collective electrical conductivity of the bundle.

Apparently, at some time toward the end of the 1890s, the prolific Canadian inventor Reginald A Fessenden (Figure 4) discovered that one can hear the electromagnetic pulses with earphones of the type used in telephones, provided one rectifies the electric current produced by the signals so that the resulting pulse contains frequencies in the audible range to which the earphones could respond. He invented a rectifier consisting of a wire dipped in an electrolytic solution. Soon after, a brilliant young Indian physicist, Sir Jagadish Chandra Bose (Figure 5), who was studying at Cambridge University when Hertz published his research and had done much to improve the coherer, patented the use of crystalline lead sulfide (the mineral galena), a rectifying semiconductor of the type discovered by Braun, as a replacement for the electrolytic device. This represented a very significant milestone in the development of solid-state electronics. Incidentally, Marconi was greatly assisted in his work by a very competent group of electrical engineers of the Italian Navy, who kept abreast of most technical developments in the field. He presumably used a semiconductor rectifier in his first successful transatlantic transmission in 1901.

In 1900 the American Telephone and Telegraph Company (AT&T) served only local communities because of limitations in the distance over which copper wire would transmit voice messages without amplification. The principal city was New York. The management of the company soon decided, however, that it should develop a national network in order to provide more uniform, consolidated service throughout the country. As a result, AT&T began to assemble an excellent technical staff to assist in determining the best route to follow. The range of possibilities included use of a wireless system. Dr. G W Pickard (Figure 6), a member of the

technical staff who had become interested in the possibility of employing wireless communication, decided to see if there was a crystalline rectifier that was superior to galena. It is reported that he investigated more than a thousand compounds. In any case, carefully selected crystals of the commercially available grade of silicon turned out to have the best properties of all the specimens included in his search. The management of AT&T permitted him to set up an independent company to market the silicon rectifiers he developed.

He became one of the foremost leaders in the field of radio technology during his time. He demonstrated the important role that resonant circuits can play in long-distance transmission. He shared a Nobel Prize with Marconi in 1909. (Courtesy of the Tuesday Morning Club of Tübingen, the library of the University of Tübingen.)

In the meantime, many scientists began to study the properties of the electron beams (cathode rays) that could be produced in a vacuum from a negatively charged electrode. One of the investigators, John A Fleming, showed that a device containing such an electron source and a positively charged collecting electrode could serve as a rectifier. Subsequently, Dr. Lee De Forest demonstrated that one could add a third electrode to Fleming's rectifier and use it to modulate the magnitude of the collected current. With appropriate feedback, De Forest's triode could be used as the basis for creating an electronic amplifier or an oscillator. Since vacuum technology was fairly primitive at the time, the early versions of the two devices behaved in an unpredictable manner and were generally treated as interesting curiosities.

However, the technical staffs of AT&T and the General Electric Company, as well as scientists and engineers in other countries, recognized the importance of the principles involved in De Forest's invention and began to improve both vacuum tube diodes and triodes. By 1915, the telephone system established by AT&T, which incorporated greatly improved vacuum tube relay-amplifiers, was able to span the continent. By the end of World War I, essentially the entire field of electronics was in the hands of vacuum tube experts. Semiconductors were almost forgotten, although inexpensive cuprous oxide and selenium rectifiers were widely used to rectify ordinary fifty- or sixty-cycle current for special purposes, such as providing rectified current to vacuum-tube filaments. As amusement, individuals in their early teens commonly made simple, inexpensive crystal-detector radio receivers that enabled them to listen to local broadcasting stations using earphones. Galena was generally used as a rectifier in such sets. Many older boys entered the world of vacuum tube technology when they could afford to acquire such tubes.

Fortunately, semiconductors were not completely forgotten since they display two important characteristic properties: they do not need a specially designed cathode and associated energy source since some conduction electrons become free at ambient temperatures; as such, semiconductors could be fabricated into monolithic devices whose useful lifetime was not determined by burn-out or other factors that influence vacuum tubes. In continuous operation at full power, a typical vacuum tube has a lifetime of ~ 1000 h. To overcome this major limitation, a number of individuals attempted to develop a triode analog of the De Forest tube

Figure 4 Reginald A Fessenden, the prolific Canadian inventor who invented amplitude modulation (AM) radio, introduced rectification and the heterodyne principle which made it possible to alter the frequencies of electromagnetic waves. He was also responsible for the first two-way wireless transmission across the Atlantic Ocean on a steady basis and for the invention of sonar. (Courtesy of the Fessenden collection of the Archives of the State of North Carolina in Raleigh, North Carolina.)

using semiconductors prior to World War II. Some inventors succeeded in obtaining conceptual design patents for proposed devices, but none were actually “reduced to practice.”

One of the individuals who took this issue very seriously in the 1920s was Dr. Mervin J Kelly (Figure 7), who was then in charge of the production of vacuum tubes at the Western Electric Company, the manufacturing arm of AT&T. He was thoroughly conscious of the limitations of vacuum tubes and was captivated by the thought of replacing, or at least complementing, them by semiconductor devices. He decided that if he were ever made Head of the Bell Telephone Laboratories, he would establish a team to explore semiconductor-based technology fully. He became head of the Laboratories in the mid-1930s and, in keeping with his plans, hired Dr. William S Shockley, a doctoral graduate of the Massachusetts Institute of Technology, to join forces with Dr. Walter H Brattain, who was already at the Laboratories, in characterizing the properties of various semiconductors. While they made a preliminary study of cuprous oxide, they were diverted to other problems as World War II approached. Kelly’s plan was forced to await the end of the war.

Research and development in the field of radar was a major activity among scientists and engineers during World War II. Although many significant investigations were carried out earlier, the first microsecond pulsed radar was developed in 1932 by an ingenious engineer, Dr. Hans E Hollmann, who used it to study the reflections of electromagnetic waves from the ionosphere in the upper atmosphere of the Arctic region – the layers that make transmission of radio waves in the kilohertz and lower megahertz region of the radio spectrum possible over long distances on the curved earth. He observed the reflected pulses on an oscilloscope with a synchronized time sweep and found that he could pick up features of the landscape such as mountain ranges. The German Navy used this knowledge to produce its first radar system soon thereafter. It operated with wavelengths in the vicinity of 2.4 m. Dr. Robert Page achieved the first comparable development in the US at the Naval Research Laboratory in 1939, delays in funding having retarded research that was initiated in the 1920s.

It should be added that Hollmann so distrusted Hitler and his plans for world conquest that he discontinued all research that might be employed in offensive warfare and focused on medical applications of electronics. While making the shift, however, he wrote a two-volume treatise in the field of high-frequency electronics that was by far the most advanced work of its kind when it

Figure 5 Jagadish C Bose who was at Cambridge University in England when Hertz published his papers on the generation of electromagnetic waves. Bose immediately began research in the centimeter and millimeter range of wavelengths. He invented many items of apparatus that were later re-invented in the 1930s, during the early days of microwave radar. He was the first person to employ a semiconductor (galena) as a rectifier. appeared in 1936. At the end of the war, he migrated to the US at the invitation of the government and became an expert consultant to industry during the early development of transistor technology.

In the meanwhile, the British, French, and Russians were pursuing the development of radar for their own military needs. In addition to carrying on research in the meter range that was to be used in the long-range perimeter defense of their island, the British were eager to increase the resolution of radar images and decrease the size and weight of equipment for airborne and other critical uses. To achieve this purpose, they extended their research to the decimeter and centimeter range of wavelengths. Consequently, a young English engineer, Denis M Robinson (Figure 8), who had been employed in servicing British television transmitters, which had broadcast programs several times a week until 1939, found himself seconded to a secret laboratory in Scotland by The Telecommunications Research Establishment (TRE), the agency that was guiding radar development in Britain. He was instructed to produce a radar system that could operate at a wavelength of 10 cm.

The means to generate and transmit such radiation was already available. Devising appropriate equipment to process and display the return signal, however, presented a problem. What Robinson needed most was a nonlinear device, or “mixer,” that had the capability of converting the reflected return signal to a frequency that could be handled by available amplifiers and the auxiliary equipment involved in display. There was no available vacuum tube, such as a rectifier, that could serve as a mixer in the low centimeter range. Developing one during wartime would take valuable time with an uncertain outcome. He went to a University library nearby and found Hans Hollmann’s two-volume treatise mentioned above. This treatise asserted that crystal rectifiers could be useful as rectifying detectors in the centimeter range of wavelengths. Robinson remembered the use of galena from his teen years and decided to team up with Dr. H W B Skinner, previously at the University of Bristol and later also at TRE. The latter was much more familiar with the so-called solid-state devices than Robinson was. After some deliberate investigations, Skinner ascertained that selectively chosen specimens of silicon, available in its somewhat variable impure metallurgical form, would provide the answer to their immediate problem of fabricating a mixer. It is interesting to note that Dr. R S Ohl, working in the field of microwave research at the Bell Telephone Laboratories in close cooperation with Dr. G C Southworth, had recently come to the same conclusion in a search for a suitable detector, thereby reaffirming the conclusion reached by his former colleague, Dr. G W Pickard, some thirty years earlier at the start of wireless communication.

When the government of France fell before the advancing German army in May of 1940, a high-level group of French scientists and engineers had been involved in research on a very advanced form of microwave generator known as the cavity magnetron. It operated at wavelengths in the vicinity of 16 cm. At one of the last possible moments, Maurice Ponte, one of the leaders of the French group, flew their working model to England, where it added significantly to the development of the magnetron being carried on there. The French, it turned out, had not yet faced up to the problem of searching for the best heterodyne mixer in that wavelength range and marveled in their turn at the effectiveness of the silicon diodes that the British were using.

Figure 8 Denis M Robinson who decided early in WWII, and after reading the treatise on microwave technology written by Hans Hollmann, to search for a semiconductor that could serve as a suitable heterodyne mixer in the 10 cm range of wavelengths. He joined forces with HWB Skinner who determined that commercially available silicon would serve their immediate purpose adequately. (Courtesy of the book *Five Years at the Radiation Laboratory* (Massachusetts Institute of Technology, 1946). Reprinted by IEEE in International Microwave Symposium, 1991.)

Once France had fallen and Britain was isolated from any immediate help from the continent, Winston Churchill decided that he must form the closest possible relationship with the US, which was still formally neutral but was preparing to become fully armed. As a positive step, Churchill offered to share with the US all secret technical research with which Britain was involved, including its developments in radar. President Franklin D Roosevelt readily agreed to the plan and established an Office of Scientific Research and Development within the Executive branch of the government.

In further keeping with Churchill's suggestion, Roosevelt selected two highly respected scientists to head the office, namely James B Conant and Vannevar Bush, the former from Harvard and the latter from the Massachusetts Institute of Technology (MIT). One of their first steps was to create the Radiation Laboratory, a radar research and development center, at MIT, to supplement on a large scale what the British had already been developing, with particular focus on applications in the microwave region. Dr. Lee A DuBridge, an already distinguished younger scientist-administrator, was selected to be the director; he would remain so throughout the war. The laboratory was rapidly staffed by a highly selective group of scientists and engineers, many from the top ranks of university faculties.

Most of the staff of the Radiation Laboratory were not familiar with semiconductors other than in a very peripheral way, such as the crystal radio sets of their early teen years. To them, the British-made silicon rectifier-mixers that were used for frequency conversion of the returning radar signals were both a curiosity and an abomination because of the great variability of the metallurgical-grade silicon used as starting material. Many on the staff felt that they should take the time to develop vacuum tube rectifiers that would operate in the microwave region.

Fortunately, DuBridge was familiar with research on crystalline solids and called on one of the authors of this article (FS) to see if a way to salvage the situation could be found. An excellent physical chemist, Dr. C Marcus Olson (Figure 9), in the Pigments Department of the DuPont Corporation near Wilmington, Delaware, found that he could produce a form of silicon that was uniformly pure to several parts in one hundred thousand by reacting purified silicon chloride with comparably pure metallic zinc. When this form of the element was properly treated with controlled additions of other elements that influenced its electrical conductivity, it could be used to produce highly satisfactory silicon diodes on a mass-production basis (Figure 10). Moreover, DuPont was prepared to manufacture the purer grade of silicon in practical quantities.

Once this point was reached, the Radiation Laboratory added a semiconductor section under the leadership of Dr. Henry C Torrey. It followed progress in industrial production and administered an extended research program, including research on diodes made from the semiconductor germanium, the sister-element to silicon, which found very special uses in situations in which the rectifier experienced high reverse voltages. Both semiconductors permitted conductivity by both negative and positive carriers depending upon the addition of small controlled quantities of foreign elements, known as "dopants." The positive carriers ("holes") were associated with a dearth of electrons in what normally are fully occupied shells or bands of electron states in silicon. The empty

states are equivalent to bubbles in a fluid, which will move opposite to the direction of any applied forces that cause acceleration of the fluid. The two types of conductors were designated *n*-type (negative) and *p*-type (positive), respectively.

When World War II ended, Dr. Kelly returned to the secret pursuit of a semiconductor triode armed with an increased staff and the extensive new knowledge of semiconductors gained during the war. Shockley was appointed head of the group and had the good fortune to attract John Bardeen, a highly experienced engineer-physicist who possessed strong background knowledge in solid-state science, as part of the team. Brattain who knew Bardeen well joined him in a remarkably productive working partnership (Figure 11).

As a first step, Shockley attempted to develop what later became known as the field-effect transistor in which the density of carriers in the bulk semiconductor is altered by application of an electric field transverse to the direction of current. He failed to achieve the desired effect and turned to other matters, leaving his colleagues to carry on. Bardeen suspected that the failure was a result of a temperature-related shift in surface charge that compensated the applied field within the bulk of the semiconductor. He and Brattain demonstrated this by repeating the experiment at temperatures sufficiently low so that the surface charges would be frozen. Much later, means of stabilizing the surface charge at normal operating temperatures were found and the resulting “field effect transistor” became an important member of the transistor family.

While extending this research in December of 1947, Bardeen and Brattain invented, partly by chance, what became known as the “point-contact transistor.” It was the first truly amplifying semiconductor triode. Shockley returned to research in this field at this point and invented what became known as the “discrete *p-n* junction transistor.” The principles involved in its operation were to play a major role in the development of electronics during the next decade.

In the course of events, one of the members of the Laboratories developed a method for purifying germanium to a very high level that was particularly applicable to that element. As a consequence, Shockley mandated that all research on transistors under his direction be carried out with crystals of germanium. A courtly strong-minded Texan on the staff, Dr. Gordon K. Teal (Figure 12), aware of the superior chemical and physical properties of silicon from wartime research, began to produce single crystals of it surreptitiously in his laboratory. Teal shifted his activity to Texas Instruments Incorporated, in Dallas, Texas, in 1953 when that company obtained a license from AT&T to produce transistors. The company gave him a warm welcome in his pursuit of the work on silicon. Methods were soon found to purify silicon to parts per billion and to improve crystal perfection, which Teal knew to be very important. The element became the mainstay of production of transistors, particularly when the beneficial characteristics of its relatively stable oxide were fully appreciated. Nevertheless, much research continued to be carried out with germanium. In fact, discrete transistors made of silicon or germanium were manufactured throughout much of the 1950s.

The invention of the integrated circuit by Jack Kilby (Figure 13) in 1958, led to previously unforeseen increases in circuit complexity, eventually at very low cost – a process requiring a good part of a decade. It was not clear at first whether such circuits, which permitted the creation and interlinking of vast arrays of transistors on a single silicon chip, would find uses other than in military applications where a premium price might be acceptable. By the mid-1960s, however, the most farsighted manufacturers began to express optimism. For example, in 1964 Patrick E. Haggerty, the President of Texas Instruments, published a paper in the Proceedings of the Institute of Electrical and Electronics Engineers in which he stated that if the remaining problems of large-scale production were resolved in an economical manner, one could expect devices based on the use of integrated circuits to become “pervasive” in human affairs, creating a revolution in such matters as information processing, communications, and controls. A year later Dr. Gordon E. Moore, then at Fairchild Semiconductor and later a founder of Intel, had the foresight and courage to predict that the cost of integrated circuits would soon go through a period in which the cost per transistor would be halved about every eighteen

months, accelerating their use. Widespread applications of the device finally reached Moore's expansive stage by the end of the 1960s, along with the rapid growth in sophistication of the technology associated with design of operating systems and applications software, the linchpins of the computer era. The end of the evolution of this field is not yet in sight. All evidence suggests that silicon will continue to play an unending role in electronics (Figure 14).

Abstract

The dielectric response of matter as described by Maxwell's equations incorporates on the microscopic level the properties of the material which subsequently has to be suitably averaged to be accessible to macroscopic observation. So-called local fields appear on an intermediate level which instead of the pure applied field constitute more close relation to the observable quantities and give rise to partly essential local field corrections to the results obtained from the bare applied field alone. In this chapter detailed examples are shown considering local field effects from optical bulk spectroscopy over photoemission in layered crystals to surface sensitive non-local response effects.

Introduction

If a dielectric material is exposed to an electric field, a dipole moment is established which is detected by the force the field exerts on it. It is a common experience to have felt the attraction acted by a charged external body as by a comb on one's hair. Such materials show induced polarization in an external electric field usually observed as surface charges disregarding the microscopic details of the interior. However, the field acts in the interior of the whole dielectric body and induces the polarization therein through the polarizability of the atomic constituents of the body, see Fig. 1 for a sketch of such polarization in a solid.

The well-known textbook Lorentz-Lorenz construction of the so-called local field is applied, which explicitly takes into account the presence of an induced field adding to the external field and being self-consistently determined at every point. In course of time, the Lorentz-Lorenz construction has been set on an ab initio fundament by considering the total many-body system, which also led to the quantitative determination by well-accepted definite rules though the whole problem cannot be solved in a closed manner.

From a macroscopic point of view, say, considering length dimensions in centimeters, the polarization is continuously spread over space, discontinuities arising at the edges of bounded bodies only. The total dipole moment causes a resulting induced field which adds to the external field usually screening it, i.e., reducing it within the material. Of course, the sources for the induced fields may be inhomogeneously distributed and arbitrarily macroscopically shaped. For example, a spherical solid dielectric body introduced between the plates of a condenser expels the initially homogeneous field from the interior by creating dipole charges on the surface of the sphere opposite to the condenser plates. This general macroscopic situation has its origin on an atomic scale that finally gives rise to what is called "local field effects."

From a microscopic point of view, atomic polarization constitutes the source of macroscopic polarization. The atomic polarization is localized being attached to the electronic cloud around the nuclei and showing a global distribution of the dipole moments reflecting the positions of the nuclei. The variability of local charge density created on an atomic scale relates to the notion of local fields. Thus, the local field considered here arises from the electric response of atomically structured material to an external field. It can be viewed as an induced granular field, which in the special case of a crystalline solid is structured by the details of the potential within the unit cell being periodically repeated. Such a local field occurs in insulators, as well as in semiconductors and metals (Slater, 1967). Crystallinity is a widely understood origin for the existence of local structure in the response fields, though the general atomic consistence of matter gives rise to local response fields also. However, the former are much easier to be dealt with than classifying or calculating, for example, amorphous or gaseous material.

Fig. 1 Local field that originates from the bare homogeneous electric field between two condenser plates by the sketched induced polarization P in molecular matter.

The above interpretation is not to be confused with the notion of local field as applied to a theoretical extension of the random phase approximation (RPA), which is a very common and basic approximation in the calculation of dielectric properties of general condensed matter. This also traces back to the roots of the Lorentz local field, though the emphasis does not lie on the granularity and geometric structure but on the many-body influences which affect even homogeneous systems.

$$\varepsilon_M = 1 + \frac{\alpha/\varepsilon_0}{1 - \alpha/3\varepsilon_0}. \quad (1)$$

The first achievement along both lines may be seen in the Lorentz-Lorenz formula for the macroscopic dielectric constant ε_M in terms of atomic polarizability per unit volume α with vacuum permittivity ε_0 (SI units used).

In Section “[Induced field](#)” the dielectric response in the frame of Maxwell’s equations is described. The transition from microscopic to macroscopic quantities follows in Section “[Macroscopic fields](#).” The general notion of the dielectric function within the dielectric response is set in Section “[Dielectric response](#)” which is specified according to the influence of exchange and correlation on optical spectroscopy in Section “[Exchange and correlation](#).” The appearance of local field effects in photoemission from layered crystals constitutes Section “[Photoemission from layered crystals](#)”. Section “[Nonlocal dielectric response](#)” is devoted to extending the local response to the nonlocal case followed by a few remarks to further topics in connection with local fields in Section “[Further application](#)” and a concluding Section “[Conclusion](#)”.

Induced field

For the theory of dielectrics, Maxwell’s equations of electrostatics constitute the framework

$$\text{div} D = \varrho, \text{rot} E = 0 \quad (2)$$

to be supplemented by the appropriate material’s equation, specifically

$$D = \varepsilon \varepsilon_0 E \quad (3)$$

for a linear relation between the so-called dielectric displacement D and the electric field E with dielectric constant or relative permittivity ε of the medium. The charge density ϱ refers only to the sources of the external field E_{ext} which can be written as $\text{div} \varepsilon_0 E_{\text{ext}} = \varrho$. One usually splits off the electric field from D by defining the polarization P , i.e., the dipole moment per unit volume, and the external field from the microscopic field by defining the induced field E_{ind}

$$D = \varepsilon_0 E + P, E = E_{\text{ext}} + E_{\text{ind}}. \quad (4)$$

Inserting Eq. (4) in Eq. (2) yields

$$\text{div} \varepsilon_0 E_{\text{ind}} = -\text{div} P = \varrho_{\text{ind}}. \quad (5)$$

This identifies $-\text{div } \mathbf{P}$ as the source of the induced field associating with the induced polarization charge q_{ind} , an analogue of the external charge, which is a rather trivial statement from the atomic point of view.

In principle, the electrostatic relations have to be complemented in order to deal with optics. The topic of local field effects, however, allows a reduction to the discussion of the longitudinal case, i.e., to the above equations of electrostatics, decoupling it from the transverse fields introduced by the time-dependent electromagnetic field. The approximation is valid as long as the length scale of the induced field is small compared to the optical wavelength. Transverse components are of course nonzero and need the full dielectric tensor which may be anisotropic. But the simplification occurs because the self-consistent generation of the total electric field from the applied external field (see Section “Macroscopic fields”) derives this approximation solely from the longitudinal field, for which Maxwell’s electrostatic equations are already sufficient.

The above simple relationship is, however, a compact abbreviation of the most general linear relation which should be written as

$$D_i(\mathbf{r}t) = \sum_j \int_{-\infty}^{+\infty} dt' \int d^3\mathbf{r}' \epsilon_{ij}(\mathbf{r}, t; \mathbf{r}', t') \epsilon_0 E_j(\mathbf{r}'t') \quad (6)$$

where the indices refer to the Cartesian axes of a tensor relation through ϵ_{ij} , the time integration sums up contributions of the electric field at various times to the dielectric displacement, and the space integration does similarly with respect to position. In physical terms, the tensor character relates an electric field in a certain direction to the displacement in any other direction with a specific factor, for example, as an anisotropic material would imply. The time integration takes into account a delay in the effect of the electric field on, for example, the polarization, which for a causal relation obviously implies zero ϵ for $t' > t$. Switching on a field or, in terms of Fourier transforms, an incident optical wave which as an oscillating process, excites an oscillating polarization with a weight depending on the frequency, this is the standard case of optical spectroscopy. The dependence on position in space, is the interesting quantity in view of the effects considered here. An electric field at a specific position in principle can excite polarizations everywhere and all contributions are summed up by the integral. The above quantity ϵ is usually called the microscopic dielectric constant, and “constant” is often replaced by “function” to stress the functional dependence on its variables.

Macroscopic fields

Measurements as, for example, in classical optical spectroscopy with wavelengths orders of magnitude larger than atomic distances may not resolve the atomic structure of matter, and therefore deal with spatially averaged quantities instead of the microscopic fields considered above. The averaging follows from space integration or from the zeroth Fourier component when expressing the field equations by Fourier transforms as conveniently done. Dealing with the example of a crystalline solid, the periodic repetition of the unit cell imposes this symmetry also on all observable quantities as fields, densities, coefficients of linear relations in position, space, etc., as long as the external fields are homogeneous. Then, the periodicity allows a representation of the total field by a Fourier series

$$\mathbf{E}(\mathbf{r}) = \sum_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} \mathbf{E}_{\mathbf{G}} \quad (7)$$

omitting the time or respective frequency dependence in the notation. The vectors $\mathbf{G}$ (bold face not used here at index positions) constitute the reciprocal lattice of the crystal. A nonhomogeneous external field may vary on a macroscopic scale, then $\mathbf{E}_{\mathbf{G}}$ will also depend on $\mathbf{r}$. However, the length scales of this field as well as those of the additional variations of the induced fields are large. In which case, all considerations still apply locally within ranges limited by that length scale. After the Fourier transformation the linear relation (3) reads:

$$\mathbf{D}_{\mathbf{G}} = \sum_{\mathbf{G}'} \hat{\epsilon}_{\mathbf{G}\mathbf{G}'} \mathbf{E}_{\mathbf{G}'} \quad (8)$$

where the hat is used to indicate a tensor instead of writing the Cartesian indices explicitly. If a homogeneous electric field is applied to an infinitely extended crystal, then the displacement field is constant everywhere and thus possesses only a zeroth Fourier component which is given by a suitable distribution (e.g., charged condenser plates) of its sources, the external charges. Inversion of Eq. (8) then yields

$$\mathbf{E}_{\mathbf{G}} = (\epsilon^{-1})_{\mathbf{G}0} \mathbf{D}_0 \quad (9)$$

the Fourier components of the microscopic field, i.e., local field which, in principle may spatially fluctuate on all length scales within the periodicity cell. Taking only the zeroth component of Eq. (9), one obtains the observable averaged electric field $\mathbf{E}_0$ and can write the material’s equation as

$$\mathbf{D}_0 = \frac{1}{(\epsilon^{-1})_{00}} \mathbf{E}_0 \quad (10)$$

This linear relation between averaged quantities constitutes what is called the local field effect, specifically a macroscopic permittivity ϵ_M which is the reciprocal of the (0,0) element of the inverse microscopic dielectric function matrix $\epsilon_{\mathbf{G}\mathbf{G}'}$

$$\epsilon_M = \frac{1}{(\epsilon^{-1})_{00}} \quad (11)$$

and applies to homogeneous external fields.

Furthermore, it also covers the case that the field additionally depends on $\mathbf{q}$ within the Brillouin zone describing larger length scales than the lattice length. Then also ε carries this additional dependence, (see Section “Dielectric response”). As indicated before, the derivation of Eq. (11) is valid for the longitudinal response to longitudinal fields, so the hat was omitted because it is a scalar quantity. The transverse average fields are related following a similar reasoning. The general tensor can be written as $\hat{\varepsilon}_M$ consisting of the bare ε and an added longitudinal correction which originates from the polarization by the Coulomb interaction.

$$\hat{\varepsilon}_M = \hat{\varepsilon}_{00} - \sum_{\mathbf{G}\mathbf{G}'(\neq 0)} \hat{\varepsilon}_{0\mathbf{G}}(\hat{\varepsilon}_r^{LL})_{\mathbf{G}\mathbf{G}'}^{-1} \hat{\varepsilon}_{\mathbf{G}'0}. \quad (12)$$

The quantity $\hat{\varepsilon}_r^{LL}$ is the microscopic dielectric constant matrix in reciprocal space restricted (subscript r) to the subspace of nonzero reciprocal lattice vectors. Only the longitudinal component of the tensor is involved which is denoted by the upper index, i.e., the tensor can be written as the product of the dyad $(\mathbf{q} + \mathbf{G})/\|\mathbf{q} + \mathbf{G}\| \otimes (\mathbf{q} + \mathbf{G}')/\|\mathbf{q} + \mathbf{G}'\|$ with a scalar $\varepsilon_{\mathbf{G}\mathbf{G}'}^{LL}$. Taking the longitudinal component of Eq. (12), algebraic manipulations lead back to Eq. (11), $\varepsilon_M^{LL} = 1/((\varepsilon^{LL})^{-1})_{00}$, with inversion of the whole unrestricted matrix. This generalization refers to the local field effect of optical and related spectra valid as long as the wavelength $\lambda = 2\pi/\|\mathbf{q}\|$ is much larger than the length scale of the atomic structure (Mochan and Barrera, 1985).

A main access to the structure of solids is used with optical spectroscopy (Ehrenreich, 1965). Below some examples are shown that make the general importance of local fields in a solid visible in those optical spectra.

Fig. 2 Calculated reflectivity of SrTiO₃, with local field effects included (solid) and neglected (dashed) compared to experiment (circles).

Fig. 3 Calculated absorption coefficient of Nb, with local field effects included (dotdash) and neglected (dashed) compared to experiment (circles); solid line includes XC corrections neglected otherwise.

Fig. 4 Theoretical absorption coefficient of Pt including local field effects (solid) compared with experiment (absorption: circles, XPS energy levels: |), and neglecting local field effects (dashed) (Krasovskii and Schattke, 2001).

Figs. 2 and 3 compare with experiment the optical spectra of SrTiO_3 and Nb calculated up to the vacuum ultraviolet with or without the local field effect (Krasovskii and Schattke, 1999). The importance of the local field effect in describing the experimental result is striking. To discuss these effects in simple terms, e.g. the disappearance of the huge peak at 25 eV in Fig. 2, a lucid picture is absent, as a matrix inversion is involved. The comparison of theory with experiment shows agreement with respect to the relative positions of maxima and minima, whereas the strength of the variation is smoothed by experimental broadening not considered in the theoretical calculation. It should be noted that the theoretical curves are obtained ab initio with the density-functional theory, and broadening from additional many-body corrections might also occur. Occasionally the connection with the local polarization is obvious in the spectra as shown in Fig. 4 for Pt.

A steep slope marks the onset of absorption from the localized semicore levels, $5p_{1/2}$, $4f_{7/2}$, $4f_{5/2}$, in both experiment and theory. Specifically, the $5p_{1/2}$ peak and also the relative intensities need local field effects to be included to explain the exponent. Both $4f$ peaks are considerably enhanced by the accompanying high atomic polarization of the medium. This proves its origin from local field effects, even though the overall shape of a spectrum may hide such a connection, as it often happens at low-energy excitations of valence states.

Dielectric response

Maxwell's theory describes the field from its source, i.e., the total charge. Conversely, the total field forces the positional adjustment of the charges through the laws of quantum mechanics, which is condensed into the dielectric constant ϵ . Once the bare response to a small test field is known through ϵ , the numerical evaluation of charge and field from Eqs. (2) and (10) is straightforward by using a suitable mathematical solution. Thus, one has to determine quantitatively the dielectric function. As already stated, the RPA is the basic approximation for calculating these properties ab initio with generally sufficient accuracy. The quantum mechanical change of the density $\delta\rho$ induced as a response to a change of the field δE is obtained from first-order perturbation expansion with respect to the latter. The total field must be treated here as a perturbation. Eq. (2) is used in Fourier space, $i(\mathbf{q} + \mathbf{G}) \cdot \delta\mathbf{D}(\mathbf{q} + \mathbf{G}) = \delta\rho(\mathbf{q} + \mathbf{G})$, and the field in Eq. (3) is replaced by its associated potential, $\delta E(\mathbf{q} + \mathbf{G}) = -i(\mathbf{q} + \mathbf{G})\delta\phi(\mathbf{q} + \mathbf{G})$. Then, the induced charge is given by the difference between total charge $\delta\rho_{\text{tot}} = \epsilon_0 |\mathbf{q} + \mathbf{G}|^2 \delta\phi$ and external charge $\delta\rho$ with the result

$$\sum_{\mathbf{G}'} (\mathbf{q} + \mathbf{G}) \cdot (\hat{1} \delta_{\mathbf{G}, \mathbf{G}'} - \hat{\epsilon}_{\mathbf{G}, \mathbf{G}'}(\mathbf{q}\omega)) \cdot (\mathbf{q} + \mathbf{G}') \delta\phi(\mathbf{q} + \mathbf{G}') = \delta\rho_{\text{ind}}(\mathbf{q} + \mathbf{G}) / \epsilon_0. \quad (13)$$

This has to be compared with the expression obtained for the induced charge from the perturbation expansion, which finally leads to

$$\epsilon_{\mathbf{G}, \mathbf{G}'}^{\text{IL}}(\mathbf{q}\omega) = \delta_{\mathbf{G}, \mathbf{G}'} + \frac{e^2}{2\pi^2 \epsilon_0 \|\mathbf{q} + \mathbf{G}\| \|\mathbf{q} + \mathbf{G}'\|} \sum_{\lambda, \lambda'} \int_{\text{BZ}} d^3\mathbf{k} \frac{\langle \mathbf{k} + \mathbf{q} \lambda' | e^{i(\mathbf{q} + \mathbf{G}') \cdot \mathbf{r}} | \mathbf{k} \lambda \rangle \langle \mathbf{k} \lambda | e^{-i(\mathbf{q} + \mathbf{G}) \cdot \mathbf{r}} | \mathbf{k} + \mathbf{q} \lambda' \rangle}{E_{\lambda'}(\mathbf{k} + \mathbf{q}) - E_{\lambda}(\mathbf{k}) - \hbar\omega - i\hbar\eta}. \quad (14)$$

Here, a single matrix element of the dielectric function for reciprocal lattice vectors $\mathbf{G}$ and $\mathbf{G}'$ is represented by a sum over occupied λ and unoccupied λ' states and an integral over an elementary cell (Brillouin zone) of the reciprocal lattice in an expression which, of course, reminds of the quantum mechanical perturbation theory. It contains the denominator for the energy difference between the

ground and the excited states of the system including the photon energy $\hbar\omega$, and the numerator with the matrix elements for a transition between both states caused by the phase factor of the Fourier decomposition of the perturbing potential. The wave vector $\mathbf{q}$ which is confined to the first Brillouin zone appears only once as an independent variable of ε which is diagonal with respect to it. Owing to translational symmetry, charge and field can differ in total momentum only by reciprocal lattice vectors. One observes again that only longitudinal fields are involved in this electrostatic treatment and consequently only longitudinal components $\varepsilon^{LL'}$ of the dielectric tensor

$$\varepsilon_{G,G'}^{LL}(\mathbf{q}, \omega) = \frac{(\mathbf{q} + \mathbf{G})}{\|\mathbf{q} + \mathbf{G}\|} \cdot \hat{\varepsilon}_{G,G'}(\mathbf{q}, \omega) \cdot \frac{(\mathbf{q} + \mathbf{G}')}{\|\mathbf{q} + \mathbf{G}'\|} \quad (15)$$

are accessed. They constitute, nevertheless, the dominant contributions in the domain of optics and related fields.

Exchange and correlation

As mentioned before, the notion of local field effects can also be applied to the many-body extensions of RPA. A treatment of the many-body corrections goes beyond perturbational approximations such as the RPA and the microscopic details change. Various partial summations of the perturbational series and additional decoupling mechanisms are to be applied. In this contribution here, a more detailed description is not tried because of its complexity. For simplicity, the main work is usually directed toward homogeneous systems though special quantitative calculations also exist for solids. In Fig. 3, such corrections for considering exchange and correlation (XC) which go beyond RPA are shown. The observed influence is rather small compared to the usual local field effects. The comparison of ab initio calculations with experimental spectra still leaves many questions open and the importance of many-body corrections depends on the details of the considered system and is an active field of present research.

Here, one development may be mentioned that is related to layered materials which are known for their special two-dimensional behavior and their respective correlation enhancement. The pump-probe excitation spectroscopy of transition metal dichalcogenide monolayers show local field structures of excitonic origin at a few electron volts. The local field is ascribed there to the polarization of an exciton population, e.g., in a MoSe₂ monolayer (Katsch et al., 2020; Rodek et al., 2021). Local field effects are observed in layered materials also at higher energies as described in more detail in the subsequent section.

Photoemission from layered crystals

In this section, TiSe₂ is chosen as a typical representative of the layered transition-metal dichalcogenides. Exciting a solid by a photon of frequency ω , the emitted photocurrent in an angle-resolved experiment is generally written as

$$\mathbf{j}(\mathbf{R}, E) = \frac{e^2}{16m^2c^2} \frac{e\hbar}{2\pi m} \lim_{R \rightarrow R'} (\nabla_R - \nabla_{R'}) \left\langle \mathbf{R} \left| G'(E + \omega) \hat{O}_0 \hat{G}(E) \hat{O}_0^\dagger G^a(E + \omega) \right| \mathbf{R}' \right\rangle \quad (16)$$

in the one-step model (Caroli et al., 1973) denoting the photoemission process as a unique transition from the electron's initial bound state to a propagating outgoing state (Schatke and Van Hove, 2003). The latter can be identified by a low energy electron diffraction (LEED) state. The excitation operator is

$$\hat{O}_0 = \hat{\mathbf{p}} \cdot \mathbf{A}_0(\hat{\mathbf{r}}) + \mathbf{A}_0(\hat{\mathbf{r}}) \cdot \hat{\mathbf{p}} \quad (17)$$

in the dipole approximation with the vector potential $\mathbf{A}_0$ suitably screened, e.g., according to the lines discussed above to obtain A^{scr} (Leventi-Peetz et al., 1995), viz.

$$A^{scr}(\mathbf{r}, \omega) = \sum_{\mathbf{G}} e^{i\mathbf{G} \cdot \mathbf{r}} (\varepsilon^{LL})^{-1}_{G,0}(0; \omega) \mathbf{A}_0(0, \omega) \quad (18)$$

simplifying for photons of long wavelengths up to energies ω of the vacuum ultraviolet. The Fourier-transformed incident vector potential, $\mathbf{A}_0(0, \omega)$ has thus only the zero wave vector. The dielectric matrix function is calculated in RPA with subsequent inversion accounting for the local fields. The layered structure of TiSe₂ shows the strong local field effect for normal emission perpendicular to the layers and the surface, as it is plotted in Fig. 5.

This figure shows a peak dispersing between 0 and 3 eV binding energy in the theoretical emission spectra which noticeably coincides with the dispersion of a band between Γ and A in the same range of binding energies, see Fig. 5A. This agreement is also found in the measured spectra. The band consists of Se p_z orbitals in a bonding state, binding neighboring TiSe₂ layers. The wavefunction modulus of this bound state has highest amplitude all along the z direction, i.e., the normal emission direction. The latter defines the outgoing state, which couples to the initial state via $\hat{\mathbf{p}} \cdot \mathbf{A}_0$, where the momentum operator is associated with the outgoing electron. Thus, normal emission picks up the surface perpendicular component of the photon amplitude, in our case of the 45° incidence of p-polarized light, i.e., polarized parallel to the plane of incident ray and surface normal. Constructive interference between both states may happen if their phases match. Imagine one of the plane waves is mainly composing the outgoing LEED state and a direct transition occurs from initial to final state with momentum conservation. Then a constructive

Fig. 5 TiSe₂ photoemission: (A) band structure for momentum direction Γ -A perpendicular to the surface layer plane, (B) calculated, and (C) measured photocurrent for normal emission with photon incidence angle of 45° toward the surface normal and photon energies as labelled at the curves. Solid lines in (B) include the screening of the photon field by the solid, whereas broken lines show the unscreened case (Bödicker et al., 1996).

phase match, if it occurs at one point, will be independent of the momentum over the whole Γ - A Brillouin zone. The binding energy of the peak will shift with photon energy, whereas its intensity remains almost constant.

The above is a rough illustration how to understand the peak in Fig. 5 that is most significantly dispersing. As an important fact the photon energy lies close to the plasma frequency of 17 eV where ϵ approaches zero and its inverse becomes large. As a consequence one expects enhanced local fields A^{scr} from Eq. (18) leading to an enhanced spectroscopic response.

For completeness, the interpretation of the other peaks is added. They originate mainly from the high density of states which appears at the high symmetry points Γ and A where the slope of an emitting band vanishes, and from the flat bands appearing at 0 and 4 eV binding energy. The latter are connected with layer-parallel orbitals.

Angle resolved photoemission spectroscopy (ARPES) reflects the local fields themselves as they cause specific photoexcitations, but also depends sensitively on the nonlocal multipole plasmon generation. Their main effects are observed near the plasma frequency and can attain an order of magnitude change.

Nonlocal dielectric response

The term nonlocal response can be taken literally as a far reaching effect of a local perturbation. The local field effects stem from considerations under the restriction of smoothly varying external fields on a macroscopic scale, i.e., long wavelengths ($q = 2\pi/\lambda \approx 0$). This condition is relaxed here. However, both effects interfere in the experiment and one has to be discerning in its interpretation. A change of the field at one site can result in changes of the dielectric displacement at very distant sites, which, of

course, is also contained in the general dependence of Eq. (6). As this dependence of the field on the charges is provided by a nonlocal long range relation, Coulomb's law, each local internal polarization by the field causes induced fields and hence, dielectric displacement everywhere. This holds in the static as well as in the dynamic case where the plasmon excitation is a very prominent long-range feature.

This rather general theoretical effect (Forstmann and Gerhardt, 1986) will not be easily detected in measurements on homogeneous systems, it becomes visible by local perturbations as, for example, a surface imposes (Feibelman, 1982). There the surface may be the source for plasmon waves which travel into the bulk and modulate the field. In addition, even below the plasmon frequency multipole surface plasmons enhance the frequency-dependent nonlocal response. The theoretical treatment, essentially governed by Eq. (6), can be based on Eq. (13) with the potential representing the full self-consistent field (SCF) in time-dependent local density approximation (LDA)

$$\delta\varphi_{SCF} = \varphi_{ext} + \delta\varphi + \delta V_{XC}. \quad (19)$$

Self-consistency is imposed by coupling the self-consistent potential $\delta\varphi_{SCF}$ to the induced charge density as before in RPA, see Eq. (13), with Poisson's equation through $-\Delta\delta\phi = \delta\varrho_{ind}/\epsilon_0$, and by using the exchange-correlation potential in LDA through $\delta V_{XC} = V_{XC}'(\varrho_0)\delta\varrho_{ind}$ (Liebsch, 1997). Because of the surface, translational symmetry is broken in one direction and calculation is restricted to real space in that direction utilizing an iterative process based on self-consistency. The centroid $d_{\perp}(\omega)$ of the charge density is suitable to characterize the surface response, i.e., it yields the position of the electromagnetically effective surface by its real part and the absorbed power by its imaginary part. For a jellium model, it shows a resonance at ~ 0.8 of the plasma frequency. The combined effect of local fields and nonlocal response shows a rather complex behavior as seen in Fig. 6.

The excitation from an external field localized just below the surface extends into the bulk with a penetration depth increasing with frequency and attains long-range behavior first at the surface plasma frequency ($\hbar\omega = 6.7\text{eV}$) and above the bulk ($\hbar\omega = 9.2\text{eV}$) plasma frequency. Closely around the surface, a dipole charge distribution establishes, which is replaced by a complex multipole behavior above the bulk plasma frequency. The granularity in the depth dependence reflects local field effects. Typical implications of the effect of the nonlocal fields at the surface on the photoemission intensity are illustrated in Fig. 7.

Further application

In addition to traditional optical spectroscopy, the reflection anisotropy/difference spectroscopy (RAS/RDS) offers surface-sensitive optical tools for access to details of the electromagnetic response. Local field effects are of importance not only in optical and related

Fig. 6 Susceptibility of Ag (111) slab, i.e., charge density at varying depth z from the surface at $z = 0$ as response to a local excitation potential at z' with lateral wave vector q , plotted vs excitation frequency, model potential used for bulk (Silkin et al., 2004).

Fig. 7 Band structure analysis of the photoemission from the surface state at $\bar{\Gamma}$ on Be(0001) according to Krasovskii et al. (2010) (a) Complex band structure of Be(0001) along the $A\bar{\Gamma}A$ interval: thick lines show Bloch waves that contribute to LEED states. Vertical extent of the shading is proportional to the modulus (not squared) of the contribution to the matrix element from the individual partial wave. Circles indicate $k_{\perp}$ vectors of the Bloch waves at the maxima B–E. Thin lines are the bulk band structure in the $A\bar{\Gamma}A$ interval. (b) Experimental semilogarithmic intensity profile $\log_{10} J(\omega)$ (circles) of the $\bar{\Gamma}$ surface state emission according to Bartynski et al. (1985) compared to the theory with (solid line) and without screening (dashed).

spectroscopy but they strongly affect also electron spectroscopy as, for example, electron losses (EELS) or photoexcited electrons of ARUPS, as shown above. The loss function of EELS

$$S(\mathbf{q}, \omega) = -\text{Im} \frac{1}{\varepsilon_M(\mathbf{q}, \omega)} \quad (20)$$

measures the macroscopic ε_M . The development of photonics toward the nanoscale regime opened the door to the details of the position dependence of electromagnetic response. For example, small metallic particles close to a molecule on a surface may produce surface enhanced Raman scattering (SERS) of that molecule by many orders of magnitude, because the field considerably increases in this geometrical configuration. At sufficiently small scales, nonlocal effects will become important such that the full dielectric function will be needed for theoretical considerations there also. Many interesting developments are affected by local fields or affect the visibility of local fields. Such considerations as e.g. nonlinear optics or composite materials go beyond the present contribution and deserve a presentation itself.

Conclusion

The term “Local Field Effects” has been related to its frequently used applications in order to describe effects of macroscopic fields induced in the microscopic electrical response on the atomic scale. The generalization of the Lorentz-Lorenz formula associates the dielectric displacement from the external charges with the microscopic field by a linear relationship that includes the polarization induced by the presence of matter. The procedure links microscopically the external charges to the vacuum electrostatic field according to Maxwell’s equation and takes into account its influence on the atomic material by quantum mechanical laws. This is a self-consistent loop connecting the total electric field with its vacuum sources, external as well as polarization charges: the field that is produced by charges produces parts of them itself. In simple terms: external charge $\Rightarrow$ external field $\Rightarrow$ total charge $\Leftrightarrow$ total field.

The relationship denoted by a dielectric function is considered here as linear, leaving e.g. nonlinear optics out of scope. Nevertheless, the linear case is fundamental and important. Thus, one has to include the linear polarization fields in basic investigations of condensed matter as in optical or in electron photoemission spectroscopies in order to get reasonable agreement with observation as shown in this contribution.

Abstract

After definition and discussion of the symmetry and basic properties of the linear complex dielectric susceptibility and permittivity tensors in crystals, their main possible types of frequency dispersions up to the visible range are described. Then various material types with pronounced dielectric properties (ferroelectrics, relaxors, dielectric – conductor composites) are briefly discussed.

Key points

- Definition and general properties of the linear complex dielectric function;
- Kramers-Kronig dispersion relations and sum rules;
- Fluctuation – dissipation theorem;

- Models of the dielectric dispersion;
- Dielectric response of homogeneous materials;
- Effective dielectric response of inhomogeneous materials and effective medium approximation.

Introduction

In this chapter we introduce the linear dielectric response of solids and briefly summarize its main functional and symmetry properties. The main discussion is devoted to the frequency dependence of the long-wavelength ($\mathbf{k} = 0$) complex dielectric permittivity and its modeling up to the infrared - visible range due to the polar phonons and free charges and at the lower-frequency range due to the charged localized defects, polar nanoregions and structural disorder. The effective dielectric response of inhomogeneous materials is discussed within the effective medium approximation with a focus to giant permittivity phenomena.

Definition and general properties of the dielectric susceptibility and permittivity

Electromagnetic field in a condensed matter medium is described by Maxwell equations containing charge densities $\rho(\mathbf{r}, t)$ and currents of electrons and ions in the medium. Dependence of charge density on the macroscopic electric field (averaged over local field variations due to the discrete atomic structure) constitutes a material relation characteristic for the material. The charge density

[☆]Change History: July 2022. J Petzelt and I Rychetsky prepared the update.

can be expressed by means of the dipole moment vector per unit volume (polarization) $\mathbf{P}$ or by the electrical displacement vector $\mathbf{D}$ (Fröhlich, 1958):

$$\rho = -\text{div}\mathbf{P}, \mathbf{D} = \varepsilon_0\mathbf{E} + \mathbf{P} = \varepsilon_0(\chi + 1)\mathbf{E},$$

where ε_0 is the permittivity of vacuum and χ is the linear dielectric susceptibility tensor. Applying generally spatial and time dependent electric field $\mathbf{E}(\mathbf{r}, t)$, the polarization vector in the linear approximation is (Fröhlich, 1958)

$$P_i(\mathbf{r}, t) = \varepsilon_0 \int_{-\infty}^t dt' \int d\mathbf{r}' \chi_{ij}(\mathbf{r} - \mathbf{r}', t - t') E_j(\mathbf{r}', t')$$

and may depend on the spatial surrounding (non-local response) and history of $\mathbf{E}$ (for causality reasons only on previous times). Assuming space and time homogeneity, the dependences are only on the differences $\mathbf{R} = \mathbf{r} - \mathbf{r}'$ and $\tau = t - t'$. Defining the time and spatial Fourier transform of the field $E_i(\omega, \mathbf{k}) = \int_{-\infty}^{\infty} dt \int d\mathbf{r} E_i(\mathbf{r}, t) e^{i(\omega t - \mathbf{k}\mathbf{r})}$, the Fourier components (i.e. plane waves) of polarization and electric displacement are $P_i(\omega, \mathbf{k}) = \varepsilon_0 \chi_{ij}(\omega, \mathbf{k}) E_j(\omega, \mathbf{k})$ and $D_i(\omega, \mathbf{k}) = \varepsilon_0 \varepsilon_{ij}(\omega, \mathbf{k}) E_j(\omega, \mathbf{k})$, where the linear dielectric function (relative dielectric permittivity or dielectric constant) $\varepsilon_{ij}(\omega, \mathbf{k}) = \delta_{ij} + \chi_{ij}(\omega, \mathbf{k})$ and susceptibility $\chi_{ij}(\omega, \mathbf{k})$ are complex functions of the real $\mathbf{k}$ -vector and angular frequency ω :

$$\varepsilon_{ij}(\omega, \mathbf{k}) = \delta_{ij} + \int_0^{\infty} d\tau \int d\mathbf{R} \chi_{ij}(\mathbf{R}, \tau) e^{i(\omega\tau - \mathbf{k}\mathbf{R})}.$$

The dielectric function describes the linear relation between $\mathbf{D}$ and the macroscopic electric field $\mathbf{E}$.

The frequency and $\mathbf{k}$ -vector can be mathematically considered as complex quantities. Since the fields are real, the dielectric function in non-magnetic materials (magnetic susceptibility is zero) fulfills the relation $\varepsilon_{ij}(\mathbf{k}, \omega) = \varepsilon_{ij}(-\mathbf{k}^*, -\omega^*)^*$ or, for real ω and $\mathbf{k}$, $\varepsilon_{ij}(\mathbf{k}, \omega) = \varepsilon_{ij}(-\mathbf{k}, -\omega)^*$. In non-gyrotropic (i.e. without optical activity) media, where $\varepsilon_{ij}(\omega, \mathbf{k}) = \varepsilon_{ij}(\omega, -\mathbf{k})$, the dielectric function tensor is symmetric $\varepsilon_{ij}(\omega, \mathbf{k}) = \varepsilon_{ji}(\omega, \mathbf{k})$. If the wave vectors obeys the constraint $ak = \pi a/\lambda \ll 1$, where a is of the order of the characteristic system inhomogeneities (in crystals the interatomic distances), the dielectric function can be expanded in ak :

$$\varepsilon_{ij}(\omega, k) = \varepsilon_{ij}(\omega) + O((ak)^2) \approx \varepsilon_{ij}(\omega).$$

Neglecting the second term on the right-hand side we assume that the response is local so that we neglect the spatial dispersion effects. Then only the frequency dependence has to be considered:

$$\varepsilon_{ij}(\omega) = \delta_{ij} + \int_0^{\infty} d\tau \chi_{ij}(\tau) e^{i\omega\tau}.$$

In most cases of practical interest for macroscopically homogeneous media this approximation is well justified (Landau and Lifshitz, 1960) and we shall limit our further discussion to this case.

The complex dielectric function (complex permittivity) has the real and imaginary part, $\varepsilon_{ij}(\omega) = \varepsilon'_{ij}(\omega) + i\varepsilon''_{ij}(\omega)$, which are even and odd functions of real ω , respectively:

$$\varepsilon'_{ij}(\omega) = \varepsilon'_{ij}(-\omega), \varepsilon''_{ij}(\omega) = -\varepsilon''_{ij}(-\omega).$$

It is a symmetric second-rank tensor which in crystals along the principle optical axes reduces to complex scalar properties (Nye, 1985). Further we shall discuss only these properties.

In the case of capacitor, the real part of the dielectric function describes its capacity and the imaginary part determines the rate of losses of the radiation energy which is (Landau and Lifshitz, 1960)

$$Q = \frac{1}{2} \varepsilon_0 |E(\omega)|^2 \omega \varepsilon''(\omega).$$

In the case of electromagnetic waves, the real part describes the change of the wavelength compared to that in vacuum ($\lambda \propto 1/\sqrt{\varepsilon'}$) and the imaginary part its absorption (attenuation).

Instead of the dielectric function, the AC electric conductivity tensor $\varepsilon_{ij}(\omega) = i\sigma_{ij}(\omega)/\varepsilon_0\omega$ can be equivalently used. Along the principal axes of the dielectric tensor in non-magnetic media, where the magnetic permeability $\mu = 1$, also the complex index of refraction $\hat{n}(\omega) = \sqrt{\varepsilon(\omega)} = n(\omega) + i\kappa(\omega)$ is frequently used to describe the dielectric response at optical frequencies. Here n is the real refractive index and κ index of absorption (characterizing the wave attenuation factor within one wavelength).

Kramers-Kronig relations

The causality principle provides analyticity of $\varepsilon_{ij}(\omega)$ in the upper complex half-plane (in the lower half-plane $\varepsilon_{ij}(\omega)$ has singularities, mostly simple poles) and results in Kramers-Kronig dispersion relations (Landau and Lifshitz, 1960):

$$\varepsilon'_{ij}(\omega) - \delta_{ij} = \frac{2}{\pi} \text{P} \int_0^{+\infty} \frac{x \varepsilon''_{ij}(x)}{x^2 - \omega^2} dx$$

$$\epsilon_{ij}''(\omega) - \frac{\sigma_{ij}(0)}{\epsilon_0 \omega} = -\frac{2\omega}{\pi} \mathcal{P} \int_0^{+\infty} \frac{\epsilon_{ij}'(x) - \delta_{ij}}{x^2 - \omega^2} dx.$$

Checking the validity of Kramers-Kronig relations is an important issue for experimentalists measuring independently the real and imaginary part of the dielectric response even in somewhat limited frequency range (Milton et al., 1997).

Sum rule

Finite charges in the medium of interest result in so called sum rule for the oscillator strengths (*f*-sum rule) (Landau and Lifshitz, 1960):

$$\int_0^{\infty} \omega \epsilon_{ij}''(\omega) d\omega = \delta_{ij} \frac{\pi}{2} \omega_p^2, \quad \omega_p^2 = \frac{Ne^2}{m\epsilon_0}$$

$$\int_0^{\infty} \epsilon_{ij}'(\omega) d\omega = \delta_{ij} - \frac{2\pi^2}{\epsilon_0} \sigma_{ij}(0).$$

where N is the density of charges e and m their mass (assuming for simplicity only one type of charges of uniform density). These sum rules are of practical importance when discussing temperature or pressure dependences of the dielectric function which undergoes pronounced changes (e. g. metal-insulator and superconductive phase transitions), since the total charge in the system is conserved.

Fluctuation – Dissipation theorem

Dielectric function is closely related to thermal fluctuations of the polarization characterized by the autocorrelation function $\langle \delta P_i(t) \delta P_j(0) \rangle$, the Fourier component of which

$$S_{ij}(\omega) = \int_{-\infty}^{+\infty} \langle \delta P_i(t) \delta P_j(0) \rangle e^{i\omega t} dt$$

is called the spectral density function. This function is proportional to dynamic structure factor measured in inelastic neutron scattering experiments and to inelastic light scattering (Raman and Brillouin) cross section. The fluctuation - dissipation theorem (Kubo, 1957) relates this function to dielectric losses:

$$\epsilon_0 \epsilon_{ij}''(\omega) = \frac{1}{2\hbar} \left(1 - e^{-\hbar\omega/kT} \right) S_{ij}(\omega) \approx \frac{\omega}{2kT} S_{ij}(\omega),$$

where the last approximation is valid in the classical high-temperature limit $kT \gg \hbar\omega$.

Polaritons

Dielectric function $\epsilon(\omega, \mathbf{k})$ describes the dielectric response to the plane-wave electric field $E(\omega, \mathbf{k})e^{-i(\omega t - \mathbf{k}\mathbf{r})}$, which can be in principle realized for arbitrary values of ω , $\mathbf{k}$ by using appropriate external electric charges and currents. When we limit ourselves to propagating electromagnetic waves in macroscopically homogeneous media, the values ω , $\mathbf{k}$ become mutually dependent. E.g., for transverse waves $\mathbf{E} \perp \mathbf{k}$, which propagate along the optical axes, $k(\omega)^2 = \frac{\omega^2}{c^2} \epsilon(\omega)$. Such waves, whose propagation is characterized by a complex wave vector, characterize mixed electromagnetic and lattice vibrational (phonon) or electron excitations called polaritons (Hopfield, 1958; Barker and Loudon, 1972). Knowing the complex dielectric function, the polariton dispersion branches are fully determined.

Physical mechanisms and models of dielectric dispersion

Dielectric function provides direct and important information about the polarization mechanisms in the medium. In all systems the dominant dispersion and absorption mechanism in the high-frequency optic range (visible and/or ultraviolet) is caused by electronic excitations (transitions from populated to empty electron levels). Since these transitions involve the whole Brillouin zone, there are no simple phenomenological models used for the description of this dispersion. Instead, microscopic calculations based on the known or calculated electron band structure are usually used and compared with experiment.

In the infrared range, the dominating dispersion and absorption mechanism in dielectrics is due to lattice vibrations (one-phonon absorption). Only polar phonons connected with the long-wavelengths dipole-moment fluctuations in the E direction, i.e. transverse phonons whose eigenvectors have polar vector symmetry, are infrared active. Their dielectric response can be well described by that of classical damped harmonic oscillators. Assuming s infrared active (i.e. polar) phonon modes, the dielectric function in approximation which neglects the mutual coupling among the oscillators is a simple sum of individual oscillator responses (Barker Jr., 1975):

$$\varepsilon(\omega) = \varepsilon(\infty) + \sum_{j=1}^s \frac{\omega_{pj}^2}{\omega_{TOj}^2 - \omega^2 - i\gamma_{TOj}\omega}$$

where $\varepsilon(\infty)$, ω_{pj}^2 , ω_{TOj} , γ_{TOj} is the high-frequency (optic) permittivity due to electronic transitions, oscillator strength (square of the mode plasma frequency), square root of the force constant and damping of the j -th transverse optical phonon mode, respectively. A more general function frequently used particularly for fitting the experimental infrared reflectivity, is so-called factorized form of the dielectric function (product of generalized oscillators) (Lowndess, 1970):

$$\varepsilon(\omega) = \varepsilon(\infty) \prod_{j=1}^s \frac{\omega_{LOj}^2 - \omega^2 - i\gamma_{LOj}\omega}{\omega_{TOj}^2 - \omega^2 - i\gamma_{TOj}\omega},$$

where the frequencies and dampings of longitudinal optical phonons are introduced explicitly. All the parameters are real positive numbers. For nonzero damping, the transverse and longitudinal eigenfrequencies correspond to complex poles and zeros of the dielectric function, respectively. Only in the limit of small dampings the eigenfrequencies approach the corresponding ω_{TO} and ω_{LO} frequencies. In the static limit $\omega = 0$, the factorized dielectric function yields the generalized Lyddane-Sachs-Teller relation. It shows that high values of the static permittivity can be reached particularly by low ω_{TO} frequencies. This is the case of displacive ferroelectrics, where the Curie–Weiss divergence $\varepsilon = C/(T - T_C)$ is achieved by softening of the soft phonon mode $\omega_{TO}^2(\text{soft}) \propto T - T_C$ (Cochran law) (Cochran, 1960).

In highly conducting materials (metals) the lattice response is screened by free charges (electrons) and their absorption dominates up to the infrared range. It can be usually well described by the simple Drude response (Ziman, 1972):

$$\varepsilon(\omega) = \varepsilon(\infty) - \frac{\omega_p^2}{\omega(\omega + i\gamma)}.$$

It is the response of a damped harmonic oscillator for zero force constant. The zero of this dielectric function is called screened plasma frequency (plasmon eigenfrequency) and characterizes longitudinal oscillations of the free carrier plasma density. Notice that unlike the case of oscillators, contribution of the Drude term to the static permittivity is negative.

Below the lattice absorption range no polarization (absorption) mechanism exists in an ideal non-piezoelectric dielectric crystal. In piezoelectric crystals the coupling between polar optic and acoustic waves activates the acoustic waves in a finite sample, which provides additional dielectric resonances, typically in the MHz frequency range, whose frequencies are, however, sample size and shape dependent (Gonzalez et al., 2016).

However, structural disorder and strong lattice anharmonicities or all kinds of movable charged defects usually induce further dispersion in the microwave and lower frequency range. Such dispersion is as a rule of relaxation type, the simplest model being the Debye relaxation (Jonscher, 1999):

$$\varepsilon(\omega) - \varepsilon(\infty) = \frac{\omega_p^2}{\omega_0^2 - i\gamma\omega} = \frac{\Delta\varepsilon}{1 - i\tau\omega}$$

where $\tau = \gamma/\omega_0^2$, $\Delta\varepsilon = \omega_p^2/\omega_0^2$ are relaxation time and dielectric strength, respectively. It is seen that in the low-frequency range $\omega \leq 1/\tau$ this function approaches that of the oscillator with frequency ω_0 and damping γ . If the oscillator is overdamped (pure imaginary eigenfrequency for $\gamma \geq 2\omega_0$), the dielectric losses are peaked approximately at ω_0^2/γ like the Debye relaxation. This frequency characterizes the dynamics of the defects or hopping frequency of the localized charges. In more complex cases, distribution of Debye relaxations has to be used to fit the broad-band dielectric spectra. In these cases, frequently appearing e.g. in polymers, much effort was exerted to study the universal dispersion laws which rule the tails of the broad loss peaks. However, till now no generally accepted picture has been achieved.

The simplest model which yields the Debye dispersion in solids is hopping of charges over a potential barrier E_a much higher than the thermal energy kT . If the charges do not interact, its temperature dependence is described by the Arrhenius law $\tau = \tau_\infty \exp(E_a/kT)$. If the charges interact, the effective barrier for hopping increases on cooling and the temperature law is usually modified either to phenomenological Vogel-Fulcher law $\tau = \tau_\infty \exp(E_a/k(T - T_g))$ or to critical slowing-down $\tau \propto 1/(T - T_C)$. Here T_g is the glass transition (freezing) temperature (Berthier and Biroli, 2011) and T_C the critical temperature (connected e.g. with an order-disorder ferroelectric transition (Kamba, 2021)) where the relaxation time tends to infinity. In the latter case the systems tend to order below T_C and the relaxation gradually vanishes. In the former case the long-range order is prohibited by some frustration due to the structural disorder so that the disorder remains frozen down to low temperatures (glass phase (Berthier and Biroli, 2011) and relaxor ferroelectrics (Bokov, 2012)) and becomes non-ergodic.

Dielectric response of homogeneous materials

The static permittivity (dielectric constant) of homogeneous solids may acquire values reaching from ~ 2 up to the order of 10^6 . Materials from both ends of this broad spectrum are required for contemporary microelectronic applications: low-permittivity materials (Grill et al., 2014) like organosilicate films for advanced on-chip interconnects and high-permittivity materials as energy

storing capacitors, tunable ferroelectric films and low-loss ceramics for microwave passive elements in communication systems. As discussed above, the permittivity value is determined by several usually positive contributions in the dielectric spectra. In low-permittivity materials both electronic and vibrational contributions are very weak, which is typical for weak bonding among non-polar molecules in organic substances. In high-permittivity dielectric materials for energy storage applications (Yang et al., 2019; Zou et al., 2019) mostly the vibrational contribution of strong low-frequency polar modes dominates, since the electronic contribution ϵ_∞ is always relatively small due to high frequencies of the electronic transitions. Also, the order-disorder ferroelectrics may reach high permittivity values close to T_C , but these are usually of no practical use because of strong temperature dependences of ϵ' and high losses. The most perspective high-permittivity materials are relaxor ferroelectrics (special type of structurally disordered ferroelectrics), where only a short-range polar ordering is reached and the dominant dielectric dispersion is due to the high-frequency dynamics of the polar nano-clusters. In doped semiconducting materials, the permittivity may also acquire giant values at low frequencies (so called giant or colossal permittivity materials (Lunkenheimer et al., 2010; Petzelt et al., 2012)), but, due to the high losses, this effect is so far not much used in applications.

Effective dielectric function of inhomogeneous materials

In the case of macroscopically or mesoscopically inhomogeneous media (e.g. nanocomposites, ceramics and films with granular structure) the standard experimental techniques cannot determine the bulk dielectric functions of individual constituents, but only so-called effective dielectric function. Historically, most frequently this function was modeled by using various equivalent schemes of parallel and series combinations of capacitors and resistors. The disadvantage of this approach is that the physical interpretation of individual capacitors and resistors is not always clear and, moreover, they are assumed to be frequency independent, which usually limits their use to relatively low frequencies (below the MHz range). Instead of this, the effective dielectric function can be more realistically determined using so-called effective medium approximation (EMA) (Bergman and Stroud, 1992; McLachlan et al., 2000), if the probing electric field is homogeneous on the scale of inhomogeneities and the boundaries between homogeneous regions are sharp. Within this approximation, the effective dielectric function still must obey the Kramers-Kronig relation and sum rules. EMA is justified as long as the wavelengths of the probing wave are much larger than the individual homogeneous parts and, in the case of absorbing components, also the local penetration lengths (skin depth) should be much larger than the sizes of all the homogeneous parts. Examples of inhomogeneous materials for which the EMA can be used could be ceramics and all kinds of micro- and nano-composites with the grain sizes of the order of μm or less. In slightly conducting systems also the grain boundaries as well as the interface layers between the electrodes and sample may play an important role, which are known to be source of the Maxwell-Wagner relaxation phenomena (McLachlan et al., 2000) at low frequencies. In ceramics, the inhomogeneity is usually just due to the grain anisotropy in the case of non-cubic grain structures, or due to different properties (mainly conductivity) of grain bulk and grain boundaries. The case of uniaxial grain anisotropy is equivalent to a composite of isotropic components, whose dielectric functions are equal to the principal dielectric functions of the anisotropic grains.

The most used EMA model, so called Bruggeman model for a two-component composite (Bruggeman, 1935), consists of two types of spherical particles with dielectric functions $\epsilon_1(\omega)$, $\epsilon_2(\omega)$ and volume fractions x , $1-x$, respectively, embedded into the effective medium. In this case the effective dielectric function $\epsilon_{\text{eff}}(\omega)$ is given by

$$x \frac{\epsilon_1 - \epsilon_{\text{eff}}}{\epsilon_1 + 2\epsilon_{\text{eff}}} + (1-x) \frac{\epsilon_2 - \epsilon_{\text{eff}}}{\epsilon_2 + 2\epsilon_{\text{eff}}} = 0.$$

In a general treatment within EMA, so called Bergman approach (Bergman, 1978), the effective response of any two-component composite with dielectric functions ϵ_1 and ϵ_2 of volume fractions x_1 and x_2 ($x_2 = 1-x_1$) respectively, can be separated into three additive parts:

$$\epsilon = V_1 \epsilon_1 + V_2 \epsilon_2 + \int_0^1 v_{12}(n) \frac{\epsilon_1 \epsilon_2}{(1-n)\epsilon_2 + n\epsilon_1} dn$$

with

$$V_1 + V_2 + \int_0^1 v_{12}(n) dn = 1$$

and

$$V_1 + \int_0^1 (1-n) v_{12}(n) dn = x_1, \quad V_2 + \int_0^1 n v_{12}(n) dn = x_2$$

The first two terms on the right-hand side describe the responses of pure components just weighted by factors $0 \leq V_1 \leq x_1$ and $0 \leq V_2 \leq x_2$. This part does not depend on the depolarizing field and corresponds therefore to the volume parts (clusters) which

are macroscopically percolated in the direction of probing E . $v_{12}(n)dn$ represents the clusters characterized by the depolarization factor n , $0 < n < 1$. $v_{12}(n)$ function, so called spectral function, characterizes the shape, topology and interactions of individual homogeneous components. All acceptable dielectric mixing formulas correspond to a particular choice of V_1 , V_2 and $v_{12}(n)$.

If the difference between complex responses of both components is pronounced, particularly strong changes in $\varepsilon_{\text{eff}}(\omega)$ appear near the percolation threshold (Nan et al., 2010) of the higher-response component, which in the Bruggeman EMA model appears for $x = 1/3$. In ceramics and films the percolation threshold of the bulk grain properties cannot be reached (if each grain is separated from its neighbors by the grain boundary with different dielectric properties) and therefore the effective dielectric spectra of high-permittivity or semiconducting materials are often strongly influenced by the grain boundaries. For instance, combining semiconducting grains with insulating boundaries can lead to effective giant permittivities (up to $\sim 10^6$) with strong dielectric relaxations at low or medium frequencies (Petzelt et al., 2013; Rychetsky et al., 2020), which are absent in the response of both bulk components.

Conclusion

After introducing the linear complex dielectric response and its basic properties, the main permittivity contributions to it and their frequency dependences up to the infrared range and their modeling are discussed. It is shown that the largest permittivity contributions in homogeneous materials are due to soft phonon modes and/or critical relaxations near the ferroelectric phase transitions, whereas the largest contributions in inhomogeneous materials are usually due to conductivity inhomogeneities, which are the main sources of giant permittivity phenomena.

Acknowledgments

The research has been supported by the Czech Science Foundation (Project LA 20-20326L) and by Operational Programme Research, Development and Education (financed by European Structural and Investment Funds and by the Czech Ministry of Education, Youth and Sports), Project No. SOLID21 – CZ.02.1.01/0.0/0.0/16_019/0000760. Abstract

This chapter discusses the fatigue behavior and mechanisms of materials. It provides an overview of the various empirical, linear elastic fracture mechanics (LEFM) and data-science approaches to estimating fatigue properties of materials. The empirical approaches are stress- and strain-based, and variable-amplitude. The LEFM approaches are by the crack growth rates and fracture mechanics models. The concept of short and long crack problems are briefly highlighted. The chapter identifies current application of data science based machine learning (ML) models use to predict fatigue behavior. The ML techniques are supervised, unsupervised and reinforcement learning. The fatigue behavior of the emerging field of complex concentrated alloys are also discussed with implications for future research directions highlighted.

Key points

- Stress-based and strain-based approaches are the empirical methods for estimating fatigue behavior of mechanical components.
- Stress-life (S–N) approach is used for components with fatigue life exceeding $\sim 10^3$ cycles, while assuming only elastic strains in the loaded component with no plastic strains included. The method is quantitative with significant computational errors.

- Strain-based approach assumes the strain range to provide the overarching mechanisms that controls fatigue. The plastic strains are used to quantify the structural response to fatigue.
- The rate of crack growth occurs when the crack-tip stress intensity factor, K , exceeds the fracture toughness of the material under the linear elastic fracture mechanics framework.
- Machine learning based neural networks and support vector machines are used to model fatigue behavior with input variables being mean stresses and environmental factors. Data are categorized as training and testing datasets. The training datasets are experimental data mined from literature and used to teach the model, whereas the test data is mainly for validation of the model.
- Three distinct fatigue behavior for complex concentrated alloys (CCAs) based on crystal structure and microstructural features are observed. The low fatigue resistance of face centered cubic CCAs is attributed to the competing effects of initiated cracks resulting from multiple slips systems and annealing/deformation twins.
- For the BCC CCAs, fatigue cracks are initiated at the grain boundaries which then propagates through the grains for body centered cubic CCA due to their limited slip systems.
- There is pronounced phase transformation in the vicinity of the crack tip associated with metastable CCAs with associated work hardening, which induce crack tip blunting.
- The fatigue and fracture mechanisms of multi-phase CCAs with mostly eutectic and non-eutectic structure shows crack initiations at the phase boundaries and persistent slip bands (PSBs). The crack propagation paths are straight or branched depending on the microstructural features.
- Conventional long crack growth models overestimate fatigue behavior of additively manufactured components, whereas the short crack models are more ideal with crack sizes of ~ 100 μm applicable for defect-based fatigue estimation criterion.

Introduction

Fatigue is a deleterious damage mechanism that occurs in advanced engineering structural components subjected to alternating loadings (Suresh, 1985, 1998). Fatigue damage is driven by initiation and propagation stages (Laird and Smith, 1962). Different types of fatigue mechanisms have been identified in structural components, based primarily on loading conditions and prevailing loading environment. Most of these fatigue mechanisms manifest as fretting, dwell, thermomechanical, and multi-axial (Suresh, 1998).

The result of fatigue failures is high casualty numbers and major financial losses. In fact, over 80% of mechanical failures in engineering structures and components are attributed to fatigue failures (Soboyejo, 1988). Attempts to eliminate or reduce the incidence of fatigue failures have been the principal driving force behind the tremendous amount of research investments into the investigation of the initiation and propagation stages of fatigue (Soboyejo, 1988).

Research in fatigue began over a century and a half ago following a series of industrial and railway accidents and the desire to reduce incidence of such failures (Klenam et al., 2022). Much of the research was driven by the desire to understand the premature failures of components subjected to cyclic loading conditions at stress levels that were substantially below the pertinent design loads under monotonic loading.

The first systematic study of fatigue failures is usually attributed to the German engineer, A Wöhler (1858–1871) (Wöhler, 1855, 1870). In his preliminary studies, Wöhler concluded that when subject to cyclic loading conditions, the strengths of steel railway axles were lower than their static strengths. Thus, the fatigue life was determined by the load range and not by the maximum load, as previously suggested (Wöhler, 1855, 1870).

Ewing and Rosenhain, and Ewing and Humphrey conducted the first mechanistic studies of fatigue (Ewing and Humfrey, 1903; Ewing and Rosenhain, 1900). In their studies conducted on Swedish iron, they identified the stages of fatigue crack initiation and propagation. In a series of investigations, they inferred, from published optical micrographs of the surfaces of cyclically damaged specimens, that slip bands developed in the grains of polycrystalline materials subjected to alternating loads. They inferred that these slip bands increased with fatigue deformation, leading ultimately to crack formation (Ewing and Humfrey, 1903; Ewing and Rosenhain, 1900).

Empirical models for characterizing fatigue damage evolution were developed by many researchers over the years to provide tools for the modeling of fatigue behavior. For instance, Basquin developed stress-based laws to characterize stress-life (S - N) curves of metals (Basquin, 1910). He showed that a log-log plot of stress versus cycles exhibited a linear relationship over a large range of stresses.

Coffin and Manson, working independently in the early 1950s, noted that plastic strains were primarily responsible for cyclic damage (Coffin, 1954; Manson, 1953). They proposed an empirical relationship between the number of load reversals to fatigue failure and the plastic strain amplitude. This formulation, known also as the Coffin-Manson relationship, is the most widely used approach for strain-based characterization of fatigue damage. Coffin and Manson also found that the plastic strain-life data can be linearized on a log-log scale. These relationships were combined to relate total strain range to life-to-failure. This relationship is called the strain-life relation. In the strain-life approach, the transition fatigue life represents the life at which the elastic and plastic strain ranges are equivalent.

The mathematical framework for the quantitative modeling of fatigue failure came later and was primarily driven early by the stress analyzes work of Inglis (Inglis, 1913) and later by the energy concepts of Griffith (Griffith, 1921). This was followed by the work of Irwin (Irwin, 1957). Irwin showed that the amplitude of the stress singularity ahead of a crack could be expressed in terms of the stress intensity factor, K . This formulation was developed based on the representation of the crack-tip stresses by the stress functions proposed originally by Westergaard (1939), and the elasticity solutions of Love (1888, 1901).

Paris and co-workers observed that the increment of fatigue crack advance per stress cycle, da/dN , can be related to the range of the stress intensity factor, ΔK , under constant amplitude cyclic loading (Paris and Erdogan, 1963). This observation set the stage for the direct application of linear elastic fracture mechanics to fatigue problems. In this approach, fatigue damage is characterized by fatigue cracks under conditions of small-scale plastic deformation at the crack tip (Paris and Erdogan, 1963). When gross plasticity occurs at the crack tip, the problem is one amenable to elastic-plastic or plastic analysis.

Elber provided further insights into the application of linear elastic fracture mechanics (LEFM) to fatigue (Elber, 1970). In studies of fatigue crack growth that were conducted by him as a graduate student in Australia, he noted that fatigue cracks could remain closed, even under cyclic tensile loads. He showed that the effective value of ΔK given by (Eqs. 1 and 2) controls the fatigue crack growth rate, da/dN . Note that K_{cl} and K_{op} are the respective crack-closure and crack-opening stress intensity factors.

$$\Delta K_{eff} = K_{cl_{max}} \quad (1)$$

$$\Delta K_{eff} = K_{op_{max}} \quad (2)$$

Further progress in fatigue investigations led to the breakdown of the similitude concept, in which cracked components in different dimensions were assumed to exhibit the same amount of crack growth, when subjected to the same far-field stress intensity factor range, ΔK . Following the pioneering work of Pearson, small cracks were found to exhibit anomalous crack growth behavior, with relatively fast growth rates occurring at ΔK level below the long crack fatigue threshold (Pearson, 1975).

Mechanisms of fatigue

Fatigue crack initiation

In most engineering structures and components, regions of high stress concentration are preferred crack initiation sites. The formation of microcracks around notches, scratches, inclusions, and along or across grain boundaries represent the onset of fatigue damage evolution. In metallic structures, microcracking is often driven by slip processes. Ewing and Humfrey referred to these slip bands as persistent slip bands (PSBs) (Ewing and Humfrey, 1903), in reference to the fact that these bands were restored after electropolishing and then re-fatiguing. Fatigue crack initiation can occur by any one of the following identified processes (Soboyejo, 1988; Suresh, 1998):

1. From regions of localized strain hardening or softening resulting from slip step accumulation occurring at the surfaces of structures subjected to high plane strain amplitudes.
2. Formation of intrusions and extrusions on the surfaces of engineering structures resulting from sequential slip at the intersection of slip planes (Cottrell and Hull, 1957; Soboyejo, 1988).
3. Microcrack formation along crystallographic planes of maximum shear stress by mode II mechanisms (Forsyth and Ryder, 1960).
4. The coalescence of microcracks to form macrocracks, which are amenable to LEFM characterization (Forsyth and Ryder, 1960).

Fatigue crack propagation

Fatigue crack propagation generally occurs in two stages, namely stage I and II. In stage I, crack propagation rate is characterized by low stress intensity factors (Forsyth and Ryder, 1960). The crack growth behavior at this stage is associated with a threshold stress intensity value, ΔK_{th} , below which fatigue crack growth is negligible. Fatigue crack growth in the threshold is affected by stress ratio, frequency of loading, and prevailing environmental conditions (Suresh, 1985, 1998).

Stage II fatigue crack growth is characterized by high ΔK and long crack lengths. In this region, crack growth rates are extremely high and most fatigue life is usually expended prior to this stage. On a plot of $\log da/dN$ versus $\log \Delta K$, the stage II region is linear (Fig. 1). The Paris-Erdogan formulation is generally used to characterize fatigue crack growth within this regime. In variable-amplitude loading, the Forman and Walker fatigue crack propagation models are used (Dowling, 1990; Forman, 1972).

Empirical approaches

Stress-based

The stress-life method, based on Wohler's $S-N$ diagram, was the first quantitative approach. The stress-life approach is used in applications where the applied stress is essentially within the elastic range, and the material has a long cyclic life.

Fig. 1 Schematics of the three distinct regimes of fatigue crack propagation.

In general, the stress-life approach is used in situations where the fatigue life is more than 10^3 cycles. In addition, the stress-life approach excludes the true stress-strain behavior and assumes that only elastic strains are effective within the loaded structure. This assumption introduces significant computational errors, since plastic strains resulting from plastic deformation are a recognized crack initiation protocol. Thus, computational results using the stress-life approach are only informative when the degree of plastic straining is negligible, as in high cycle fatigue (HCF), where plastic strains are relatively small (Dowling, 1990).

Stress-life data are usually represented by S - N curves, in which the stress range or stress amplitudes are plotted against the log of the number of cycles to failure, N . The S - N data for body-centered cubic materials generally exhibit an endurance limit, that is, a stress below which the specimens appear to have infinite life. In the case of face-centered cubic and hexagonal-closed-packed metals, a fatigue limit is often defined as a stress corresponding to a specified fatigue life, for example, 10^7 cycles.

Strain-based

The strain-life method is one of the two classes of empirical approaches for the characterization of fatigue life in structural components. The other approach is the stress-life approach that was discussed in the preceding section. The strain-life model is based on the observation that in many structural components, the response of the material in critical locations, such as notches, is strain or deformation dependent.

Thus, the principal assumption for calculating fatigue life of a component under constant amplitude cyclic loading is that the strain range, $\Delta\epsilon$, controls fatigue life. In the strain-life approach, the plastic strain is used directly to quantify the structural response to fatigue. However, in the stress-life approach, the plastic strain is not accounted for. The strain-based approach stipulates that at long fatigue lives, beyond the transition life, N_t , the elastic strain dominates the fatigue life, while the plastic strain is negligible with increasing life. In this case, fatigue strength (σ_f'/E) dominates fatigue.

In the case of short fatigue lives, the plastic strain is dominant and fatigue ductility (ϵ_f') is the controlling fatigue parameter. In general, most engineering structures are designed such that the nominal loads remain elastic. However, due to stress concentrations around notches, localized plasticity is often encountered in engineering structures and components.

One key attribute of the strain-life approach is that it disregards the presence of precracks. Fatigue life prediction using the strain-life approach requires the following essential inputs: (1) cyclic stress-strain response and strain-life data, (2) stress-strain history obtained from critical locations such as notches, (3) damage counting techniques such as cycle counting, (4) mean stress effect models, and (5) damage summation techniques such as Miner's rule (Dowling, 1990). In the strain-life approach (see Fig. 2), the relationship between the total strain amplitude and the number of load reversals to failure is given as

$$\frac{\Delta\epsilon}{2} = \frac{\sigma_f'}{E} (2N_f)^b + \epsilon_f' (2N_f)^c \quad (3)$$

where ϵ_f' is the fatigue ductility, c is the fatigue ductility exponent, σ_f' is the fatigue strength coefficient, $\Delta\epsilon$ is the strain amplitude range, $2N_f$ is the number of load reversals to failure, and b is the Basquin's exponent.

Variable-amplitude fatigue

Under service conditions, most engineering structures and components are exposed to a host of load spectra. For instance, an aircraft under turbulent conditions may be exposed to unique load spectra, compared to the conditions that are inherent to normal operating scenarios. It is, therefore, important to design for a wide range of loading conditions that can occur under unintended and uncontrollable service conditions.

Fig. 2 Schematics of the plot of elastic and plastic strain amplitude vs. life showing total strain amplitude.

The extensive literature on fatigue crack growth shows that experimental test data often differ considerably from predictions of crack growth under variable-amplitude loading conditions (Dowling, 1990; Suresh, 1998). Under constant-amplitude loading, the crack growth increment, Δa , is dependent only on the present crack size and the applied load. However, under variable-amplitude loading, the increment of fatigue crack growth is also dependent on the preceding cyclic loading history. In most cases, the interactions that occur under variable-amplitude loading adversely affect the fatigue lives of engineering components and structures (Suresh, 1998).

LEFM approaches

Fundamentals of fracture mechanics

The concept of linear elastic fractures has been applied to the design of engineering structures for nearly five decades. LEFM assumes that the material is isotropic and linearly elastic. Based on these assumptions, the stress field near the crack tip is often calculated using the theory of elasticity (Love, 1888, 1901) and Westergaard stress function (Westergaard, 1939). Within the framework of LEFM, crack growth occurs when the crack-tip stress intensity factor, K , exceeds the material fracture toughness, K_{IC} (Irwin, 1957). LEFM formulations are usually derived for either the plane stress or plane strain conditions associated with the three basic modes of loadings on a cracked body, namely, crack opening, sliding, and tearing (Irwin, 1957; Suresh, 1998).

The formulation of LEFM assumes that under applied loading conditions, crack tips produce a $1/\sqrt{r}$ singularity. The stress fields near a crack tip of an isotropic linear elastic material can be expressed as a product of $1/\sqrt{r}$ and a function of θ with a scaling factor K (Dowling, 1990; Hertzberg, 1996; Soboyejo, 2002). The stress intensity factor plane strain formulations for mode I stress fields in Cartesian coordinates are given in Eq. 4.

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \end{Bmatrix} = \frac{K_I}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \begin{bmatrix} 1 - \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \\ 1 + \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \\ \sin \frac{\theta}{2} \cos \frac{3\theta}{2} \end{bmatrix} \quad (4)$$

In practical applications, the magnitude of the maximum stress near the crack tip and whether it exceeds the fracture toughness of a given material is usually of interest to design engineers. Hence, the stress intensity factor, K , which is a function of the loading and geometry, is expressed in terms of the “applied stresses,” σ at a location expressed in polar coordinate by $r \rightarrow 0$ and $\theta = 0$ (where r and θ are cylindrical coordinates of a point with respect to a crack tip). The solution of crack problems using the fracture toughness approach requires: (1) the determination of the crack geometry, (2) the calculation of the stress intensity factor, K , (3) the determination of the fracture toughness, K_C of the material (usually obtained from a material handbook), and (4) ensuring that the failure criteria $K \geq K_C$ is satisfied.

Fracture mechanics and fatigue

Paris and co-workers proposed that the increment of fatigue crack advance per stress cycle, da/dN , could be related to the range of the stress intensity factor, ΔK , under constant-amplitude cyclic loading (Paris and Erdogan, 1963). They formulated the relationship given by Eq. (5).

$$\frac{da}{dN} = f(\Delta K, K_{\max}()) \quad (5)$$

where

$$\Delta K = K \Delta \sqrt{\pi a}^m \min_{\max} \quad (6)$$

where $K_{\max}$ and $K_{\min}$ are the maximum and minimum stress intensity factors, respectively.

Paris and Erdogan, in their subsequent work, established that the fatigue crack advance per stress cycle could be related to the stress intensity range as follows:

$$\frac{da}{dN} = C(\Delta K)^m \quad (7)$$

where C and m are material constants.

In practical applications, two independent fracture mechanics parameters are required to characterize the state of stress at the evolving crack tip. A combination of any two of the following can be used: $K_{\max}$, $K_{\min}$, ΔK , and R .

Using Eq. (3) and assuming a constant Y , both sides of Eq. (7) can be integrated:

$$\int_{a_0}^{a_f} \frac{da}{a^{m/2}} = CY^m (\Delta \sigma)^m \pi^{m/2} \int_0^{N_f} dN \quad (8)$$

For $m > 2$:

$$N_f = \frac{2}{(m-2)CY^m (\Delta \sigma)^m \pi^{m/2}} \left[\frac{1}{(a_0)^{(m-2)/2}} - \frac{1}{(a_f)^{(m-2)/2}} \right] \quad (9)$$

For $m = 2$:

$$N_f = \frac{1}{CY^2 (\Delta \sigma)^2 \pi} \ln \frac{a_f}{a_0} \quad (10)$$

The constants C and m are material parameters that are usually determined experimentally. Typically, m values are in the range of 2–4 for most metals. For intermetallics, m is generally between 6 and 20. However, for ceramics, m can be as high as 100. For cases where Y depends on crack length, the above integrations are usually performed numerically. It is also important to note that the crack growth rate in the Paris regime is weakly sensitive to load ratio and is driven by ΔK (Soboyejo, 1988, 2002; Suresh, 1998).

The initial crack, a_0 , can be determined using non-destructive die penetrants inspection, ultrasonics, or X-ray techniques. If no cracks are detected, one can assume a crack length to be at the resolution of the detection system. The critical crack length can be determined from the failure criterion when $KC_{\max}$.

Fatigue crack growth laws

Numerous fatigue propagation (see Fig. 1) models have been developed to characterize fatigue damage evolution in engineering materials. However, none of these models capture all aspects of the mechanisms of fatigue crack propagation. For instance, the extent of crack growth over a range of stress levels cannot be determined a priori from these models. However, these models do highlight the processes associated with the crack-tip opening during crack propagation.

Forsyth and Ryder proposed that fatigue crack extensions were the result of sporadic bursts of brittle and ductile fracture and that the contribution of each mechanism to crack propagation was a function of the ductility of the pertinent material (Forsyth and Ryder, 1960). They also proposed that cracking occurs by necking, which obstructs the material until void coalescence occurs. These voids are usually created during forward cycling.

Fatigue crack propagation models include models by Paris and Erdogan (1963), Forman (1972), Walker and Elber (1970), Newman and Elber (1988). The application of these models to practical engineering situations depends on the material type and loading conditions. Paris-Erdogan and Forman's models are used for constant-amplitude loading (Forman, 1972; Paris and Erdogan, 1963), while Walker and Elber models are used for variable-amplitude loading (Elber, 1970; Newman and Elber, 1988). These variable-amplitude loading models incorporate crack-growth retardation or acceleration, and threshold effects.

Paris' model

In the mid-DK regime, the law shows that the crack advance per stress cycle is related to the stress intensity range (Eq. 11).

$$\frac{da}{dN} = A(\Delta K)^m \quad (11)$$

where A and m are material constants determined experimentally.

Forman's model

The Forman's equation is a form of the Paris' law that takes the effect of the applied stress ratio into consideration. It provides an empirical model for fatigue life estimation with mean stress effects as shown Eq. (12).

$$\frac{da}{dN} = \frac{c(\Delta K)^n}{K_f(1-R) - \Delta K} \quad (12)$$

where c is a pre-exponential constant, n is the power law exponent, K_f is a material constant, R is the stress ratio, and ΔK is the stress intensity factor range.

Walker's model

The Walker's equation also accounts for stress ratio effects. The Walker and Forman's relationships are equivalent to Paris' law when $R = 0$, and the crack growth rate depends solely on the ΔK (Eq. 13).

$$\frac{da}{dN} = c[K_{\max}^m] \quad (13)$$

where $K_{\max}$ is the maximum stress intensity factor, R is the stress ratio, c is a pre-exponential constant, m is the power-law exponent, and n is a material constant.

Multiparameter law

The multiparameter law proposes a fatigue life prediction approach using the combined effect of multiple variables on fatigue crack growth (Bhalerao et al., 2003). The formulation is based on the multiple regression analysis and involves the representation of crack growth rate, da/dN , as a multiple variable statistical expression. Examples of such variables include stress intensity factor range, ΔK , crack-closure stress intensity factor, K_{cl} , and stress ratio, R .

Elber's model (crack-closure model)

Elber formulated a crack-closure technique by modifying Paris' equation to include the dependence of the crack growth rate on the stress ratio (Elber, 1970; Newman and Elber, 1988). According to Elber, the plastic zone evolves around the crack tip, when the yield stress of the material is exceeded. Subsequently, a wake of plastically deformed material is developed and is encapsulated by the surrounding elastic medium as the crack grows. When the loaded component is being unloaded, the plastically deformed material causes crack surfaces to contact at zero tensile loads.

Elber concluded that crack closure retards fatigue crack growth rate by reducing the stress intensity range, ΔK . He introduced the effective stress intensity range, ΔK_{eff} , for use in Paris' law Eq. (14), with the modified Paris' law given in Eq. (16).

$$\Delta K_{\text{eff}} = K_{\text{op}} \Delta_{\max} \quad (14)$$

where

$$U = \frac{\Delta K_{\text{eff}}}{\Delta K} \quad (15)$$

$$\frac{da}{dN} = D[\Delta K_{\text{eff}}]^p \quad (16)$$

where $K_{\max}$ is the maximum stress intensity, K_{op} is the stress intensity at which the crack opens, U is the so-called Elber closure ratio, and D is a pre-exponential constant.

Fatigue fracture modes

The surface morphologies of fatigue cracks are classified as follows:

- *Transgranular cleavage*. This occurs along defined planes in crystal structures. Cleavage formation is the result of high stress along the three axes where significant deformation occurs at low temperatures. Cleavage morphology is characterized by cleavage steps,

feather markings, herringbone structure, and microtwins. Such morphologies are often observed in the near-threshold region (Shen et al., 2004a, 2004b; Soboyejo et al., 2004).

- *Fatigue striations.* These occur generally in the mid- ΔK and high- ΔK regimes. In general, the striation spacings correspond to the crack growth rate under HCF conditions (Fine and Ritchie, 1979; Mercer et al., 1999, 2000, 2003; Pelloux, 1970; Sinha et al., 2000; Soboyejo et al., 1995; Suresh and Ritchie, 1982). However, under low cycle fatigue (LCF) conditions striations are sometimes not definable and hence cannot be correlated with crack growth rates.
- *Combined striations and static fracture modes.* At high- ΔK levels, a combination of fatigue striations and static fracture modes is observed, with the incidence of static modes increasing with increasing ΔK . The static modes often include secondary cracks and ductile dimples that are akin to those observed under monotonic loading (Mercer et al., 2001; Pelloux, 1970; Ritchie and Knott, 1973).

The short crack problem

Studies of fatigue behavior of short cracks (Fig. 3) have attracted considerable attention since the total fatigue life of many components may be dominated by the short crack regime (Lou et al., 2001; Mercer et al., 2001; Ritchie and Lankford, 1986; Shrotriya et al., 2002; Sinha et al., 2000; Soboyejo et al., 1995; Suresh and Ritchie, 1983). These studies have altered the fatigue limit concept, from a damage limit to a critical propagation limit.

As a result of the successful application of the concepts of LEFM to the growth of long cracks, significant attempts have been made to apply similar methods to modeling the behavior of short cracks. The extent of localized plasticity, however, violates the assumptions of LEFM. This so-called short crack problem was first observed by Pearson (1975). It has been attributed to the synergistic interactions between the effects of microstructure and localized plasticity.

A classification scheme for short cracks was proposed by Ritchie and Lankford by comparing their lengths to appropriate plasticity and microstructural length scales. For instance, mechanically small cracks have lengths that are comparable to their estimated plastic zone sizes; microstructurally short cracks are those that have lengths comparable to the microstructural dimensions of the pertinent continua. Physically, short cracks refer to those cracks that have dimension of ≤ 1 mm.

Three common phenomena have been advanced to explain why small/short cracks can grow at higher growth rates than long cracks. These include: (1) limited crack-closure effects when the small crack has little or no wake ("physically small"), (2) inhomogeneous sampling of the microstructure when the cracks are smaller than relevant microstructural dimensions ("microstructurally small"), and (3) similarity between small crack lengths and the plastic zone size.

Applications of data science and machine learning to fatigue

There are four paradigms for materials development and the estimation of mechanical properties such as those associated with fatigue, as shown in Fig. 4. This section focuses on the emerging applications of data science to fatigue. This includes predictive analytics, materials information, and relationship mining.

There is increasing application of data science and machine learning in studying fatigue in structural and functional metals and alloys. This includes quantitative approaches based on statistical methods where constitutive models are fitted to large data sets

Fig. 3 Schematic of typical fatigue crack growth behavior of short and long cracks.

Fig. 4 Four paradigm for material development and mechanical property estimation.

Fig. 5 Schematic representation of machine learning approaches used to estimate fatigue of materials.

(Stinville et al., 2022). Thus, data science and machine learning provide the platform to make decisions and/or predictions through gleaning insight from data. With ~5000 years of metallurgical history and data on composition-structure-property-performance history, combined with increasing computational infrastructure, compositions and mechanical properties are easily predictable.

Machine learning approaches are being used to determine fatigue behavior of materials. These include the applications of Supervised, Unsupervised and Reinforcement Learning, as shown in Fig. 5. Supervised Learning (SL) uses historical data to make predictive analyzes. This is done by relying on the concept of learning from the past trends to predict the future. Supervised Learning is based primarily on data with labels, and is often considered to be a mature machine learning technique. It is used widely in materials science and engineering for the prediction of mechanical properties.

The two main SL approaches are regression, which is in the domain of continuous target variable, and classification under the categorical target variable data label. Therefore, SL is generally referred to as “data with label”. Unsupervised learning (UL) is an

Table 1 Typical machine and deep learning approaches for mechanical property estimation.

ML/DL Technique	Characteristics/Behavior modeled	Mechanical Property Assessed
Linear and polynomial regression	Relation between input and output parameters	Young's modulus (Yang et al., 2019), yield and tensile strength (Zhao et al., 2021).
Random forest (RF)	Decision trees	Young's Modulus (Yang et al., 2019; Zhao et al., 2021), Toughness (Lei et al., 2019; Yamasaki et al., 2021)
Support vector machine (SVM)	High-dimensional data space	Strength (Zhao et al., 2021), Hardness, Optimized structural topology (Wei et al., 2018), fatigue
Neural networks (NNs)—feedforward	Use neurons and hidden layers with one directional flow of information	Strength (Wang et al., 2019; Zhao et al., 2021), Toughness (Lei et al., 2019; Yamasaki et al., 2021), Hardness (Ravinder et al., 2020), Hyperelastic and plastic behavior (Huang et al., 2020; Yang et al., 2020)
Neural network—recurrent	Connected neurons using historical data in hidden layers for sequential flow of data	Fracture behavior in polycrystals (Liu et al., 2020) (Alipour et al., 2021)
Neural network—convoluted	Data assessment at hierarchical levels—voxel- or pixel-based dataset	Strain-stress field prediction, elastic properties of composites, modulus of unidirectional composites, strength of additively manufactured metallic components, fatigue crack propagation in polycrystalline alloys (Niu and Srivastava, 2022).
Generative adversarial networks	Two component neural network trained to generate trends in data per training dataset	Modulus distribution based on inverse elasticity problems, strain-stress fields in composites, composite design, structural topology optimization, design of architecture materials
Gaussian process regression and Bayesian learning	Input parameters treated as random variables to estimate the probability distribution. This is used to predict and quantify uncertainty	Modulus (Yang et al., 2019), strength and design of recoverable metamaterials and super compressible
Graph neural networks (GNN)	Uses non-Euclidean data for node, link, and graph classification	Hardness prediction and for the design of architecture materials

exploratory analyzes technique that is used to find hidden correlations (extract information from data without labels). In materials science and engineering, this can be within the composition—processing—structure—property relationships of alloys which are not evident in small datasets. Reinforcement learning (RL) is a process of decision making that relies on through trial-and-error interactions based on the sets of instruction in a dynamic environment. Thus, the learning agent perceive and interpret the environment, take actions, and then learn through the process in a trial-and-error manner (Kaelbling et al., 1996). Most RL are based on state and action focusing on either a model-base or model-free approaches. Typical ML processes used for estimating mechanical properties, i.e., fatigue life of mechanical components is summarized in Table 1.

The physics-guided modeling of fatigue is based on the random fatigue-limit model. This model should satisfy two conditions based on the fatigue life and applied stress (strain). These are: (i) the standard deviation of fatigue life of mechanical components decreases with increasing applied strain (stress) and (ii) the curvatures of typical fatigue curves are indicative of the incorporation of the fatigue limit in the statistical model (Chen and Liu, 2021a, 2021b). The curve is asymptotic near the fatigue limit, except for cases where there are no fatigue limits for the alloy. Considering “ N ” as fatigue life and “ s ” as stress level, then the fatigue life can be estimated using Eq. (17) (Gan et al., 2021). This is slight modification of Basquin's explicit regression model establishing the relationship between fatigue life and stress levels. The drawback of typical explicit regression models is the few parameters needed to estimate the fatigue behavior. Due to the small parameters used, functional relationship between fatigue life and applied loads are underestimated. This has stimulated the recent application of machine learning models (Chen and Liu, 2021a). Through machine learning models, additional parameters such as the notch factor, tensile and yield strengths can be included for best-fit prediction.

$$\log(N) = \beta_0 + \beta_1 \log(s - \gamma) + \varepsilon, s > \gamma \quad (17)$$

where β_0 and β_1 are coefficient of fatigue curve, γ is the fatigue limit of the specimen and the error term is ε .

Machine learning techniques that are based on neural networks have been used to model fatigue behavior (Gan et al., 2021; Huang et al., 2006, 2011). The approach uses input variables such as mean stresses and environmental factors. Machine learning algorithms are data intensive. Two categories of data are used: training and testing datasets. The training datasets are experimental data that are used to teach the model or algorithms or network. This is to extract the required features that are relevant to the problem that is being solved through a deterministic process. This is for the optimization of the hyper-parameter, which reduces the possibility of under- and over-estimation (Chen and Liu, 2021a, 2021b; Choi et al., 2021; Gan et al., 2021; Kamble et al., 2020; Luo et al., 2021). The testing data is used to check the generalized capability of model or algorithm or network to ensure the right trends, insights, and desired predictions. This is to reduce the margin of error associated with underestimation or overestimation.

The prediction of fatigue crack growth is critical for the estimation of the residual lives of mechanical components, and also for engineering failure analyzes (Klenam et al., 2022). Supervised ML-based regression models that are used to estimate crack growth rates in the Stage II and Stage III regimes include Ridge regression, K-nearest neighbor regression and polynomial regression (Kamble et al., 2020). The input parameters used for the model were ΔK and frequency of loading. The models are trained using experimental datasets. The application of polynomial and Ridge regression enables multiple features to be correlated. Hence, simple linear regression will result in overestimation of the crack growth rates.

The K-NN model is based on similarity measure. It has been used to estimate the average numerical target of the nearest neighbor. The main drawback of the K-NN is when there are more than two distinct types of variables, i.e., numerical, and categorical variables. Similarly, the accuracy of the model is dependent on pre-processing and selection of the training data, and the choice of the hyper parameter associated with the model. The hyper parameter, α , determines how best the data will be fitted to the experimental value. For fatigue crack growth rate, α is ~ 0.5 . The K-NN provided the best accuracy for crack growth rate in Regimes II and III.

ML-based neural networks have been used to estimate fatigue lives of engineering components (Gan et al., 2021; Huang et al., 2006, 2011). Neural networks with single-hidden layer are ideal for estimating the remaining fatigue lives of mechanical components within a multi-step loading approach (Huang et al., 2006, 2011). The extreme learning machine (ELM) is widely used for this purpose, as it randomizes the assignment of hidden parameters. There is no multivariate optimization process, which increases the training speed. Also, the ELM does not have any local minima associated with output error. The instability of output performance of residual life estimation of component leads to development of an enhanced ELM, which is a Kernel-Extreme Learning Machine (KELM) (Gan et al., 2021; Huang et al., 2006, 2011, 2012). The inadequacies associated with the randomization of parameters in ELM are not associated with the KELM approach, which provides the best generalization that has been used in widely (Huang et al., 2006, 2011, 2012). The KELM approach applied to over 169 experimental results was based on the implementation model given in Fig. 6. The auto-learning attribute of most KELM models makes them ideal and adaptable for estimating residual fatigue life of components with different permutation of loading conditions and material classes (Gan et al., 2021).

The data-driven approaches present more mechanistic understanding of contributions of intrinsic mechanical properties and parameters in the Basquin's empirical model for estimating fatigue life of components. The plot of experimental fatigue data for various metallic materials showed very low fatigue efficiency (normalized fatigue strength as percentage of yield or tensile strengths) (Omar and El-Awady, 2022; Stinville et al., 2022). Thus, fatigue strength of metallic materials does not necessarily increase with increasing yield or tensile strength. Failures have been observed as low as 25% of yield strength for high strength dilute and concentrated metallic alloys, as shown for some alloys in Fig. 7 (Stinville et al., 2022).

This shows the relationship between the yield strength and intensity of slip localization. Data science and ML approaches augment empirical stress- and strain-based approaches which are time-consuming and expensive.

The support vector machine (SVM) is an optimization algorithm based on supervised ML (Bao et al., 2021). It uses the structural risk minimization principle to predict the fatigue life of mechanical components. When this method is applied for regression, it becomes the support vector regression (SVR). An overview of the fatigue life prediction process based on SVM is given in Fig. 8 (Bao et al., 2021).

Overview of fatigue of complex concentrated alloys

Complex concentrated alloys (CCAs) are multiple principal elements with compositions in near equal amounts. This paradigm shift in alloy design was pioneered in Cantor et al. (2004) and Yeh et al. (2004) with other naming conventions being high entropy alloys

Fig. 6 Typical KELM implementation model used for estimating remaining fatigue life of a component (Gan et al., 2021). (HEAs) and medium entropy alloys (MEAs) (Fig. 9). Composition ranges are at the central regions of the phase diagrams of the constituent elements. While the initial hypothesis focused on equiatomic compositions, there are deviations resulting in non-equiatom and interstitial based CCAs (Akinbami et al., 2022; Klenam et al., 2022b, 2022c, 2022d, 2022e). These alloys extend the frontiers for alloy design beyond the conventional dilute alloying concentrations with potentially superior mechanical, physical and chemical properties (Klenam et al., 2022d).

Fig. 9 Schematic diagram showing the classes of complex concentrated alloys based on compositions.

Based on the crystal system and phase classification, the four classes are single phase face centered cubic (FCC), single phase body centered cubic (BCC), metastable and multi-phase CCAs/HEAs (Li et al., 2020). The single-phase FCC alloys have great ductility but poor strength, whereas the single-phase BCC alloys have high strength but poor ductility. This is mainly due to the strength-ductility trade-off associated with conventional metallic materials.

The domain of metastable and multiple phases show promise to solving the strength-ductility trade-offs. This has been attributed to deformation mechanisms associated with hierarchical and gradient microstructures with multiple and metastable phases. This induces simultaneous improvements in strengthening and toughening. Beyond strengthening mechanisms, such as solid solution, interstitials, dislocation, precipitation, grain size and back stress strengthening, other microstructural features such as microbands, nanotwinning or nanoprecipitates are great contributing factors to superior mechanical properties.

As a burgeoning field, there are few studies on fatigue behavior of CCAs. These studies have been done using standardized empirical approaches and some computational techniques based on knowledge-based and probabilistic physics-guided machine learning. The single-phase FCC-based alloys have the lowest fatigue strength due to the inherently low strength as shown in Fig. 10 (Li et al., 2020). These are comparable to Cu-, Mg- and some low strength steel alloys. Alloys with multi-phase microstructures had relatively high fatigue strength, whereas alloys with metastable phases outperformed most of the high-end conventional steels and Ti-based alloys. A typical example is the Fe—Mn—Co—Cr—Si—Cu alloy (Fig. 10). The fatigue strength is about 36% of the ultimate tensile strength (~ 1200 MPa). These fatigue behaviors are attributed to the microstructural features associated with the various crystal structures.

Fig. 10 Relationship between ultimate tensile strength and fatigue strength between some conventional alloys and the four classes of CCAs based on crystal structure and phases (Li et al., 2020). Fig. 11 Typical crack growth rate as a function of stress intensity factor where (a) schematic representation of the three regions and (b) fatigue crack growth rate of various conventional and CCAs (Li et al., 2020). From Li W, Chen S, Liaw PK (2020) Discovery and design of fatigue-resistant high-entropy alloys. *Scripta Materialia* **187**: 68–75.

The application of fatigue crack growth rate on CCAs have been studied within the three regions following the linear elastic fracture mechanic approach (Fig. 11). The CCAs with single phase FCC and BCC had the lowest fatigue crack growth rates. The complexities associated with metastable and multi-phase (duplex) CCAs lead to high fatigue crack growth rates (Fig. 11b). The mechanisms promoting these mechanical behaviors are further discussed.

The fatigue and fracture mechanisms based on the crystal structure and phase classifications (Fig. 12) (Li et al., 2020). There are intrinsic microstructural characteristics such as slip localization on the fatigue behavior of structural metals as shown in Fig. 12. The fatigue and fracture mechanisms are driven by cracks initiating along the planar slips and at twin boundaries for FCC-based CCAs (Fig. 12a). When there is initiation of cracks at multiple slips, a zig zag crack path is observed (schematically shown in Fig. 12a).

Generally, the low fatigue resistance of FCC CCAs is attributed to the competing effects of initiated cracks resulting from multiple slips systems and annealing/deformation twins. These were observed for Cantor alloy and its derivatives: CrCoFeMnNi, CrCoFeNi, CrCoFeNiMo_{0.2}. A linear dependence of fatigue strength on slip amplitude has been observed for various conventional alloys and FCC-based CCAs/HEAs. For the BCC CCAs, fatigue cracks are initiated at the grain boundaries which then propagates through the grains. Due to the limited slip systems in BCC materials, the mechanism is simple. In BCC HfNbTaTiZr, intergranular cracks nucleated at grain boundaries and then propagates in a transgranular manner. Thus, BCC alloys generally have low stress threshold (fatigue limit) and high fatigue crack growth rates.

Fig. 12 Fatigue and fracture mechanisms associated with different crystal structures of CCAs/HEAs showing (a) FCC-based, (b) BCC-based, (c) Metastable and (d) multi-phase (Li et al., 2020). From Li W, Chen S, Liaw PK (2020) Discovery and design of fatigue-resistant high-entropy alloys. *Scripta Materialia* **187**: 68–75.

In the case of metastable CCAs, the phase transformation from FCC to HCP is pronounced in the vicinity of the crack tip. This is associated with work hardening, which is critical for crack tip blunting. Within the fracture-process zone, the dynamic phase transformation promotes crack branching and deflection. In the HCP phase, there are deformation and mechanical twins formed contributing to arresting, branching and deflection of cracks during the crack initiation and propagation stages. This directs propagating cracks towards twin boundaries. Thus, the metastable phases lead to deceleration and retardation of cracks propagation, resulting in relatively high fatigue resistance.

The fatigue and fracture mechanisms of multi-phase CCAs with mostly eutectic and non-eutectic structure shows crack initiations at the phase boundaries and persistent slip bands (PSBs) (Liu et al., 2019a, 2019b; Shukla et al., 2018; Tang et al., 2015). The crack propagation trajectories along the phase interfaces are either straight or branched depending on the microstructures. Generally, the crack propagations along PSBs follows a zig-zag pattern attributed to the intersection of multiple slip systems (Liu et al., 2019a, 2019b; Shukla et al., 2018; Tang et al., 2015). If nano-sized precipitates are observed in the microstructure and along the path of propagating fatigue cracks, there is crack deflection at these precipitates. The complex microstructural features of multi-phase CCAs activate tortuous crack propagation behavior, contributing to the overall fatigue resistance. These mechanisms are schematically shown in Fig. 11d.

Overview of fatigue of additively manufactured metals/alloys

Additive manufactured (AM) or 3D printed components are being used under complex load-bearing applications in the automotive, aerospace, and biomedical industries (Kermavnar et al., 2021; Klenam et al., 2022a; Stavropoulos and Foteinopoulos, 2018; Thomas and Gilbert, 2014). However, the challenge with 3D printed mechanical components are the intrinsic defects such as lack of

Table 2 Defects, causes and characteristics features associated with additively manufactured components (Sanaei and Fatemi, 2021).

Types of defects	Causes/sources	Characteristic features
Keyholing	Excessive energy	Keyholes not properly closed
Gas porosity		Gas entrapment
Unmelted powder	Insufficient energy	Incomplete melting of powders
Lack of fusion		Non-sintered patches
Oxides particles	Oxygen contents	Oxygen entrapment
Surface roughness	Layer-by-layer deposition and feedstock	Partial melting of feedstocks
Balling phenomenon	Lack of wetting of solid particles	Material discontinuity
Secondary phases	Recurrent heating and cooling with complex phase transformation	–
Small cracks	Residual stresses	–
Bead-up	Solidification of melt as droplet lines	

From Sanaei N, Fatemi A (2021) Defects in additive manufactured metals and their effect on fatigue performance: A state-of-the-art review. *Progress in Materials Science* **117**: 100724.

fusion and gas porosities and extrinsic defects adversely affecting mechanical properties, acting as sites for crack initiation under monotonic and cyclic loading (Barroqueiro et al., 2019; Hashemi et al., 2022; Sanaei and Fatemi, 2021).

Fatigue behavior of mechanical components are sensitive to defects. These defects are intrinsic in AM parts resulting from the starting materials which are mainly powder or wire. The other factors are the layer-by-layer material deposition with associated localized heating and cooling cycles leading to differential solidification and lack of fusion. The main defects associated with 3D printed mechanical components, causes and distinguishing features (Table 2) (Sanaei and Fatemi, 2021). Postprocessing of AM parts are applied to eliminate these defects with considerable success. The challenge with postprocessing of near-net shape manufacturing techniques is the serious cost implications.

Fracture mechanics-based techniques have been used for defect-based fatigue life estimation of 3D printed mechanical components. Multiscale and multistage computational models have also been incorporated in some of these estimations (Nyshadham et al., 2019; Panchal et al., 2013). The fracture mechanics approach included defect characteristics such as size, shape, location, geometry, microstructural dependent crack growth properties and the loading information (monotonic or cyclic). In cases where there are large defects, extreme value statistics (EVS) was used to estimate the maximum or critical defect size allowable in a large volume to induce fatigue failure. This was then used to correlate the fatigue performance of mechanical components produced using the powder bed fusion AM parts.

In a 3D printed Ti6Al4V alloy, conventional long crack growth models were overestimating. Thus, short crack models with crack sizes on the scale of 100 μm were applicable for AM components considering the defect-based fatigue estimation criterion. Small cracks have lengths comparable to features at the microstructural scale. Mechanically, the length is comparable to the local plasticity scale and physically are in the order of 0.1–1 mm (Sanaei and Fatemi, 2021). For the nominal stress intensify factor, fatigue crack growth rates of short cracks are statistically significant and much higher than for the long cracks, which significantly affect the fatigue life prediction results. Short cracks can grow in Mode II, which is shear as well as mixed mode, which is critical for extracting relevant fatigue crack growth behavior other than for long cracks, which are mostly Mode I. Surface and internal defects that are critical factors that affect additively manufactured components are presented in Table 3.

Semi-empirical, phenomenological and fracture mechanics-based models are used to evaluate fatigue behavior of various classes of alloys. A typical approach is correlate the fatigue strength to the area of critical defect and the hardness (Eq. 18). Stress intensity factor and fatigue life have been estimated using micro-CT scan of defects and fractography of AM components (Eqs. 19 and 20).

$$\sigma_f = \frac{C(HV + 120)}{(\sqrt{\text{area}})^{\frac{1}{6}}} \quad (18)$$

$$\Delta K = Y\Delta\sigma\sqrt{\pi\sqrt{\text{area}}} \quad (19)$$

$$\frac{da}{dN} = C \left[\left(\frac{1-f_N}{1-R} \right) \Delta K \right]^n \left(1 - \frac{\Delta K_{th}}{\Delta K} \right)^p \quad (20)$$

where: σ_f is fatigue limit, C is a constant based on fracture mechanics based on the critical defects, HV is the Vickers hardness and $Y = 0.65$ and 0.5 for surface and internal defects.

Generally, intrinsic, and extrinsic defects, coupled with heterogeneous microstructures affect the fatigue performance of AM components considerably. These lead to scatter in fatigue life data. Hence, thorough characterization is needed to prevent under- or over-estimation of the fatigue lifetimes.

Table 3 Internal defects in AM components and their characteristics on fatigue behavior of various metallic components.

Alloy	AM Method	Defect Categories	Features and Observation
Ti-6Al-4V	SLM	Internal defects (double conical defects), gas porosity, pores, and unmelted zones	• Significant effects of the internal defects on poor fatigue performance (Gong et al., 2012). • Fatigue failure due to crack initiation at the internal defect (gas porosity) site, irrespective of applied load (Wycisk et al., 2015). • Reducing porosity improved fatigue strength of the AM component, comparable to wrought processed Ti-6Al-4V (Leuders et al., 2013). • Small defects (notches and micro-pore) lead to failure sites at earlier stages of nucleation (Brenne et al., 2013). • Fatigue crack initiation sites were at the unmelted zones near the surface with high stress concentration (Chastand et al., 2016).
	EBM	Voids, pores, entrapment of gasses	• Improved fatigue strength after hot isostatic pressing (HIP) postprocessing due to internal pores and voids (Hrabe et al., 2017). • Pores affect fatigue strength significantly, while acting as crack propagation sites (de Formanoir et al., 2016; Shui et al., 2017). • Significant deviation from optimum process parameters leading to large defects and inferior fatigue properties (Gong et al., 2015).
AISI 316L SS	SLM	Pores	• Crack growth rate and high cycle fatigue (HCF) performance were not affected by the pores due to the ductility of the alloy (Riemer et al., 2014).
Hastelloy X		Cracks, pores	• Excellent fatigue properties due to optimized process parameters and HIPing (Wang, 2012).
AISI10Mg		Pores	• Great fatigue properties irrespective of defects and imperfections (Brandl et al., 2012).
17-4 SS		Caves, crevices, pores, unmelted regions	• High thermal stress cracking resulting in porosity with adverse effect on fatigue properties (Yadollahi et al., 2017). • Unmelted regions acted as site for fatigue crack nucleation with adverse effect on fatigue strength (Gu et al., 2013).

From Sanaei N, Fatemi A (2021) Defects in additive manufactured metals and their effect on fatigue performance: A state-of-the-art review. *Progress in Materials Science* **117**: 100724.

Conclusion

The study of fatigue in mechanical components spans over a century and a half of effort and is still an ongoing process. A basic understanding of fatigue damage stages currently finds applications in various fields such as biomedical, aerospace, and automotive. With the development of new materials and manufacturing processes, the quest to develop mechanistically based life prediction protocols is intense. The short crack problem, which defies the conventional LEFM approach to fatigue modeling, needs further research to develop models that include short crack effects. Recent advances in MEMS technology will provide nano- and microscopic damage information required to develop constitutive-based life prediction protocols. Furthermore, the fatigue of CCAs is affected by microstructural features and phases. The metastable and multi-phase alloys show superior fatigue properties compared to the single-phase FCC and BCC. For AM components, the variability of defects, heterogeneous microstructure, scatter in fatigue data and uncertainties are significant. Hence, the development of defect-free models relating fatigue with microstructural features requires further work. Semi-empirical, phenomenological, and ML-based models are applicable for industrial applications and able to optimally assess the nature of defects. However, the application of ML (supervised and unsupervised learning) and multiscale models a rational and strategic approach. This will reduce the overall cost and time taken for empirical approaches to fatigue testing.

Acknowledgments

The authors are grateful to Bruce Fenton and Dale Wilson of the Federal Aviation Authority (FAA) and Dr. Carmen Huber of the National Science Foundation (NSF) for their support and encouragement of this work. Appreciation is also extended to the Worcester Polytechnic Institute (WPI) for the Global Fellowship that was awarded to Desmond Klenam.

Introduction

When we say that something is elastic we usually think that it is something that springs back to its original shape after we stretch, bend, twist, or compress it. The elastic properties of materials are those that govern the change in shape and the tendency of the material to return the bonds between atoms or molecules back to their original condition. Of course, we can exceed the level at which the material can completely recover its original shape resulting in permanent deformation (plastic deformation) or fracture. Even if plastic deformation or fracture intercedes, the shape change that the material which is elastic has undergone will reverse, returning the material back to its unstretched state.

The model for the elastic response of materials most commonly used is that of a spring. The response of a spring is well known for a linear relationship between force and displacement even to relatively large extensions or strains. When we apply this model to solid materials the mechanical response is approximately linear to very small strain levels. Although this nearly linear response may have been known for quite a long period in man's history, it was not until the seventeenth century that Robert Hooke defined the essential relation showing the proportionality between a tensile stress and the resulting tensile strain. That the changes in shape in all dimensions held similarly near linear responses became understood subsequently through the work of Thomas Young, S D Poisson, and others. [Figure 1](#) shows the linear relationships between normal stress, σ (force divided by the cross-sectional area perpendicular to it) and normal strain, ϵ (the displacement normalized to the length over which it is measured).

By the twentieth century, it became apparent that the simple relations developed to describe elastic properties could vary with the direction of loading in single crystals, oriented polycrystals, and oriented molecules. This directionality is often called anisotropic elasticity. If a material does not possess this directional variation in properties, it is called isotropic. With isotropic elasticity, only two of the material properties called elastic constants are necessary to fully describe the elastic response of a material. More recently, researchers have increasingly probed the larger strain response of materials that can be decidedly nonlinear. Many biomaterials demonstrate this extended range of elasticity that is often called hyperelasticity.

Defining Elastic Constant

Isotropic Materials

Elastic constants are the constants describing mechanical response of a material when it is elastic. The isotropic elastic constants for some common materials are given in [Table 1](#). If the engineering approximation that this mechanical response is linear is made, one can define a set of constants that relate any applied stress to the corresponding strain. When the material can also safely be treated as isotropic, the number of independent elastic constants required to completely describe the elastic response of a material is two. Any further elastic constants can then be defined in terms of the other two.

For a simple tension or compression test, the easiest elastic constant to define is Young's modulus, E . Young's modulus is the elastic constant defined as the proportionality constant between stress and strain:

$$E = \frac{\sigma}{\epsilon} \quad [1]$$

Young's modulus has the same units as stress, which is normally expressed in terms of pascals (Pa), equivalent to newtons per square meter, or pounds per square inch (psi). Strain is, of course, a dimensionless proportionality between a change in length and an original length. The Young's modulus is the slope of the linear elastic response for a number of materials as shown in [Figure 1](#).

Another elastic constant that can be obtained in a tension or compression test wherein the strain along the loading direction and orthogonal to it is called Poisson's ratio, ν . Poisson's ratio is the ratio between width or diameter strain, ϵ_1 , of a tension or

Figure 1 The stress vs. strain behavior for a number of materials measured from tensile loading experiments on commercial materials. The elastic constant called Young's modulus is the slope of each of these curves. (Adapted from Bowman KJ (2004) *An Introduction to Mechanical Behavior of Materials*. Wiley; © Wiley. Table 1 Approximate elastic properties of various materials (and dilute alloys) at room temperature

Material	Young's modulus, E (GPa)	Shear modulus, μ (GPa)	Poisson's ratio, ν
Aluminum and aluminum alloys	69–72	24–26	0.35
Copper and copper alloys	125–135	47–50	0.34
Irons and steels	205–215	80–84	0.29
Stainless steels	190–200	75–78	0.33
Titanium and titanium alloys	115	42–44	0.32
Aluminum oxide	380–390	155–165	0.25
Silicon carbide	440–460	195–200	0.14
Glass	70–90	28–32	0.27
Polyethylene (PE)	0.2–2	^a	0.4
Polymethylmethacrylate (PMMA)	2–3	^a	0.4
Polystyrene (PS)	2–4	^a	0.35
Bone ^b	5–30	3–8	0.25–0.5
Tendon ^b	0.8–1.5		

^aThese values are typically about one-third of Young's modulus.

^bBone and tendon are not only strongly anisotropic, but the stiffness also varies with type, position, and moisture content.

compression specimen and the strain along the tension or compression axis, ϵ_3 . This dimensionless proportionality constant can be written as

$$\nu = \frac{-\epsilon_1}{\epsilon_3} \quad [2]$$

So far, the possibility of stresses occurring in multiple directions have not been considered. To do so, one needs to extend the idea of assigning a coordinate system to the stress state as shown in Figure 2a. If such a multiaxial loading condition is considered, the relations between a set of normal stresses and the corresponding strains as given by Hooke's law can be written as

$$\begin{aligned} \epsilon_1 &= \frac{\sigma_1 - \nu(\sigma_2 + \sigma_3)}{E} \\ \epsilon_2 &= \frac{\sigma_2 - \nu(\sigma_1 + \sigma_3)}{E} \\ \epsilon_3 &= \frac{\sigma_3 - \nu(\sigma_2 + \sigma_1)}{E} \end{aligned} \quad [3]$$

This relation enables a set of normal stresses to be translated into corresponding strains using just the Young's modulus and Poisson's ratio.

A type of stress called a shear stress, τ , can also be defined which can produce a shear strain, γ . For shear stresses, the force is applied across the area and it results in a shearing of the material. Just as for normal stresses, shear loading can result in a mechanical response that is elastic and nearly linear, but the shape change is called a shear strain as shown in Figure 2b. The specific case in

Figure 2 (a) Normal stresses referenced to an orthogonal coordinate system (b) shear stresses and resulting distortion called shear strain.

Figure 2b shows τ_4 , which consists of a shear displacement in the y -direction on the z -face and in the negative y -direction on the negative z -face. To have a stable distortion, a similar pair of forces would need to be applied on the y -faces to cancel the rotational moment imposed by τ_4 . The elastic constant that describes the linear relation between τ and γ is called the shear modulus, μ . So, one can write

$$\mu = \frac{\tau}{\gamma} \quad [4]$$

For isotropic materials, the relation between these three elastic constants is

$$E = 2\mu(1+\nu) \quad [5]$$

Values for all three elastic constants are given for a number of materials at room temperature in Table 1. The values are given as ranges to represent variations expected from alloying.

Because elastic constants are related to bonding, they generally scale with melting temperature and the type of bonding. The strength and the type of bond determines the relationship between an applied force and changes in the distance between atoms. The spacing between atoms or molecules in a material that is not under stress comes about from a balance between attractive and repulsive forces that prevent the atoms or molecules from getting too close, and attractive forces that bring the atoms together. The sum of these two opposite forces is called the interatomic potential. Application of a stress to the material changes the balance point. Because the relationship between force and displacement is nearly linear, the elastic properties of materials can be described using linear relationships. As materials increase in temperature, they undergo increased thermal vibration that leads to thermal expansion. This increase in lattice constants also leads to a reduction in elastic constants with increasing temperature as indicated by Figure 3.

Anisotropy

When a material is anisotropic, the elastic constants vary with the direction along which the material is mechanically loaded. Even single-crystal materials have significant elastic anisotropies such that, the Young's modulus in one-crystal direction can be much

Figure 3 The dependence of Young's modulus on temperature for a number of materials. The curve for iron shows the values of Young's modulus for the three phases found in iron as a function of temperature. (Adapted from Bowman KJ (2003) *An Introduction to Mechanical Behavior of Materials*. Wiley; © Wiley. This material is used by permission of John Wiley and Sons, Inc.)

different from that along another crystal direction. For example, in copper, elastically stretching the crystals along the cube axes of its unit cell requires one third as much stress as along the body-diagonal of the unit cell to produce the same strain. In iron single-crystals, the ratio between the smallest and largest Young's moduli is over two.

Because many engineering applications use materials that are comprised of many crystals or polycrystalline, the impact of directional processing (rolling, vapor deposition, extrusion, etc.) on producing elastic anisotropy was only recognized fairly recently. Developing ways to describe the relationship between oriented polycrystalline materials and the intrinsic single crystal properties has been an important area of research. Many newer applications of materials, including single crystals of superalloys used at high temperatures in jet turbines and the single crystals used in silicon computer chips, employ materials that have strongly anisotropic elastic properties.

Fiber-reinforced polymer composite materials possess directional properties that correspond to the arrangement of the fibers, which are normally stiffer than the polymer matrix material. Although models for fiber composite materials have existed for many years, their predictive capacity is often limited. The effects of the interfacial bonding, fiber arrangement and size scales, and their influence on anisotropic elasticity are not particularly well understood.

The importance of including elastic anisotropy in predictions of performance has also entered in evaluation of elastic constants of natural composite materials such as bone. Like nearly all natural materials, directional growth processes lead to elastic anisotropy. This elastic anisotropy depends on the type of bone, location on the bone, and the age of the bone. All three of these factors affect the ratio between the collagen and mineral contents of bone. The elastic properties and corresponding anisotropy have been increasingly recognized in the increasing fragility of bone with age and bone diseases, such as osteoporosis.

Defective growth patterns that occur in osteoporosis, bone diseases such as cancer or Paget's disease, can lead to bones with reduced elastic properties and strength. The mineral crystal content of bones is critical to maintaining stiff and strong bones. Bone mineral density (BMD) is measured to evaluate the condition of bone in aging patients, and provides a very potent indicator of decreasing elasticity and greater likelihood of bone fracture. One of the recently recognized limitations of bone density measurements is that it does not take into account the detailed structure of the bone mineral content, which can strongly affect the elastic properties of the bone. The morphology and preferred orientation of the bone mineral content results in strong elastic anisotropy such that the Young's modulus of a bone along its length can be nearly twice that in the radial direction. This anisotropy also plays a role in the lifetime of joint replacements. Many knee and hip replacements are principally constructed of metals or ceramics that have much higher elastic stiffnesses and lower degrees of anisotropy than does bone (see Table 1). The mismatch in elastic properties can lead to failure of the hip replacement.

Specification of the anisotropic elastic constants are usually facilitated through writing tensor relations between stress and strain. When the elastic constants are specified such that individual stresses are reported in terms of strains, the coefficients are called stiffnesses, c_{ij} , such that

$$\sigma_i = c_{ij}\epsilon_j \quad [6]$$

In eqn [6] the strain term on the right-hand side is the sum of all possible values of j .

When the elastic constants are written such that the individual strains are reported in terms of stresses, the coefficients are called compliances, s_{ij} , such that

$$\epsilon_i = s_{ij}\sigma_j \quad [7]$$

In eqn [7], the stress term on the right-hand side is the sum of all possible values of j . The Young's modulus is the inverse of the compliance since a single applied stress can be related to the strain in the same direction, for example, for a stress applied in the x -direction.

$$\epsilon_1 = s_{11}\sigma_1$$

Measuring Elastic Constants

For isotropic materials, direct measurements of elastic constants as shown in Figure 1 is an effective approach to evaluate elastic constants such as Young's modulus and Poisson's ratio. Using tension and compression tests to measure anisotropic elastic constants requires testing of multiple specimens at a number of orientations. Easier approaches use other characteristics of the material that are related to elastic properties.

Probably, the easiest approach for measuring the anisotropic elastic constants of materials is to use measurements of sound velocity in a material. By transmitting ultrasound pulses and measuring the time it takes for the pulse to propagate through the material, a quick and easy assessment of the elastic properties can often be made. When waves are propagated through a material, they interact with the mass of the atoms and the strength of the bonds between the atoms. The number of independent elastic constants required to fully describe the elasticity of materials is directly related to the symmetry of the crystals. For cubic crystals, three independent elastic constants are required to describe the elastic constants. For crystals and bulk materials with orthogonal symmetry (such that the character of the materials can be described by an orthogonal coordinate system), at least nine independent elastic constants must be determined.

Two types of waves are readily propagated through the bulk of materials, normal waves and shear waves. When normal waves are propagated through a material in the x -direction, the velocity is related to the normal stiffness as

$$v_1 = \sqrt{c_{11}/\rho} \quad [8]$$

where ρ is the density and c_{11} is the normal stiffness. The normal stiffness c_{11} relates a stress to a strain in the same direction when the material is constrained such that, all other strains are held to zero.

For shear waves the velocity is related to the shear stiffness by the relation

$$v_4 = \sqrt{c_{44}/\rho} \quad [9]$$

A recent development has been finding the anisotropic elastic constants using the resonant frequencies of crystals. The technique can be accomplished on a single specimen by oscillating the sample over a wide range of frequencies and finding the resonant values.

Increasing interest in nanoscale materials has led to the development of techniques to evaluate the elastic constants of thin films and particles of materials on size scales approaching a nanometer. Carbon nanotubes, which are derived from research on carbon C_{60} or "bucky balls," consist of several hundreds of carbon atoms and have diameters in the order of 1 nm. Many early predictions of their elastic properties overpredicted the Young's modulus. The planar structure of graphite leads to a very high Young's modulus within the planes of 1000 GPa and a Young's modulus across the planes that is more than a hundred times lower. The elastic constants of carbon nanotubes are also strongly anisotropic with values along the tube axis of several hundred GPa and values in the radial direction of less than 10 GPa.

Similar challenges in assessing the elastic properties are apparent in thin films as nanoindentation and scanning microscopy processes usually produce load versus displacement relations that are nonlinear due to loading geometry. When the loading behavior is modeled, it is often difficult to directly compare the elastic constants recovered to those for bulk materials. This can lead to scientists erroneously deciding that the thin film possesses an elastic behavior different from what is observed in the bulk. Thin film effects and other scaling impacts on elastic properties should always be evaluated carefully.

The Fundamental Nature of Elastic Constants

The details of the relationship between bonding and the elastic properties of materials has become more interesting as measurement techniques have improved and computer modeling has become more sophisticated. It has long been understood that elastic constants decrease almost monotonically as materials undergo greater thermal vibration at higher temperatures (see Figure 3). Once the melting temperature is reached the material loses its ability to support a load and the elastic constants fall to zero.

The balance between attractive forces and repulsive forces is often modeled with relatively simple expressions that can fail to accurately predict thermal expansion and elasticity and their temperature dependences. Although the approximate temperature dependence shown in Figure 3 is useful for engineering calculations, in careful measurements, the elastic constants change rapidly as phase transformations are approached. It is apparent that the thermodynamic changes that occur at a phase transformation are signaled by strongly nonlinear changes in properties as the phase transformations are approached. The effects of alloying elements on elastic properties in solid solutions have also been shown to depend on the electronic structures of the materials, relative atomic radii, and other details of the components.

Many of the most advanced models for elastic response rely on constructing computer models that simulate the atomic arrangement in the material with assigned bonds between each of the atoms. Then virtual experiments can be conducted on a computer to simulate either the direct elastic response or the response of the lattice to wave propagation.

Extremes of Elasticity: Hyperelasticity

Materials with more than one type of fundamental bond, for example, ceramic and polymeric glasses, and materials tested under conditions at which they can sustain very high stress levels without failure, can become decidedly nonlinear in their response. Understanding this nonlinearity and its effects of material performance has resulted in the study of what is called hyperelasticity. Hyperelastic responses are particularly observable in compressive loading with superposed hydrostatic stresses and complex localized stress states such as plane strain fracture and indentation loading. Many models for mechanical processes that rely on assumptions of linear elasticity may require substantial modification to describe the effects of hyperelasticity.

Nomenclature

b	Burgers vector
F	external force
G	shear modulus
K	Peach–Koehler force (scalar)
K	Peach–Koehler force (vector)
l	instantaneous length of the specimen
l_0	original length of the specimen
M	Taylor factor
q	instantaneous cross section of the specimen
q_0	initial cross section of the specimen
s	dislocation line vector
S	dislocation structure
T	temperature
T_m	melting point
V_i	volume fraction of the cell interiors
V_w	volume fraction of the cell walls
α	geometric constant
γ	shear strain
Δl	change in length of the specimen
ϵ	strain
$\dot{\epsilon}$	strain rate
ν	average velocity of a dislocation
ρ	dislocation density
ρ_m	mobile dislocation density
σ	stress
σ_i	flow stress in the cell interiors
σ_w	flow stress in the cell walls
τ	shear stress

Deformation Fundamentals

Crystallographic Slip

Metals are crystalline except for very special conditions. Metals and alloys generally crystallize in a face-centered cubic (f.c.c.), body-centered cubic (b.c.c.), and hexagonal close-packed (h.c.p.) crystal structure. There is unambiguous evidence that metals retain their crystal structure during plastic deformation. This conservation principle of crystal plasticity has serious consequences for the deformation process and material properties. In a noncrystalline material, a macroscopic shape change can be accommodated on an

Figure 1 Plastic deformation of crystals (dotted lines=unit cell): (a) with change of crystal structure; (b) by crystallographic glide; and (c) by deformation twinning.

atomistic level by a respective atomic rearrangement. If a macroscopic deformation of a crystal is also copied on an atomistic level, the crystal structure would change (Figure 1a); this is however contrary to observation. The crystal structure can be conserved, if the shape change on an atomistic level is accommodated by a displacement along crystallographic planes in multiples of translation vectors of the crystal lattice (Figure 1b). This phenomenon is referred to as crystallographic glide (or crystallographic slip). As a result, crystal plasticity proceeds by a structure conserving simple shear deformation. In principle, there are an infinite number of planes and translation vectors to accomplish an imposed shape change. Due to energetic reasons, crystallographic glide is confined only to a few crystallographic planes (slip planes) and directions (slip directions), normally the most densely packed planes and directions in a crystal. A slip plane and a slip direction constitute a slip system and the most prominent slip systems of the three major crystal structures of metals are given in Table 1. The mechanism of crystallographic glide is related to the motion of crystal dislocations. The glide plane of a dislocation and the direction of its Burgers vector correspond to the slip plane and slip direction, respectively. On an atomistic level, therefore, plastic deformation of a metal requires the generation and motion of crystal dislocations.

Table 1a Slip systems of the major metallic crystal structures

Crystal structure	Slip plane	Slip direction	Number of nonparallel planes	Slip directions per plane	Number of slip systems
f.c.c.	{111}	$\langle 1\bar{1}0 \rangle$	4	3	$12=(4 \times 3)$
	{110}	$\langle \bar{1}11 \rangle$	6	2	$12=(6 \times 2)$
b.c.c.	{112}	$\langle 11\bar{1} \rangle$	12	1	$12=(12 \times 1)$
	{123}	$\langle 11\bar{1} \rangle$	24	1	$24=(24 \times 1)$
	{0001}	$\langle 11\bar{2}0 \rangle$	1	3	$3=(1 \times 3)$
h.c.p.	{10 $\bar{1}$ 0}	$\langle 11\bar{2}0 \rangle$	3	1	$3=(3 \times 1)$
	{10 $\bar{1}$ 1}	$\langle 11\bar{2}0 \rangle$	6	1	$6=(6 \times 1)$

Table 1b Twinning systems of the major metallic crystal structures

Crystal structure	Twinning plane	Shear direction	Displacement plane	Displacement plane
f.c.c.	{1 1 1}	$\langle 112 \rangle$	$\langle 110 \rangle$	Ag, Cu
b.c.c.	{1 1 2}	$\langle 111 \rangle$	$\langle 110 \rangle$	α -Fe
h.c.p.		$\langle 10\bar{1}1 \rangle$		Cd, Zn

Dislocations are crystal defects and, therefore, cause a distortion of the atomic arrangement, which manifests itself into a long-range stress field. Via their stress field, dislocations interact with each other. This constitutes a glide resistance, which is macroscopically felt as a yield stress and eventually causes immobilization of moving dislocations. The traveling distance (slip length) of a moving dislocation is normally much smaller than the macroscopic dimension of the deformed body; therefore, dislocations are stored in the crystal and the dislocation density grows with progressing deformation which in turn increases dislocation interaction and thus the flow stress. The relation between flow stress σ and dislocation density ρ can be represented by the Taylor equation

$$\sigma = \alpha M G b \sqrt{\rho} \quad [1]$$

where the dislocation density ρ (m^{-2}) is defined as the total dislocation line length per unit volume – typically 10^{10}m^{-2} for annealed and 10^{16}m^{-2} for heavily deformed metals, b is the Burgers vector (slip vector), G is the shear modulus, and M is the Taylor factor which relates the applied stress to the shear stress in the glide system and depends on crystallographic texture (see below). Typically, $M \sim 3$, and the geometrical constant $\alpha \sim 0.5$.

Any change in the glide resistance of the moving dislocations will affect the flow stress. This is the reason for work hardening (increasing dislocation density), other strengthening mechanisms (grain size, solute atoms, particles, precipitates, etc.), and softening by recovery and recrystallization (decreasing dislocation density). It is important to note that the macroscopic deformation behavior can be related to the microscopic properties of the crystal dislocations. The force K on a dislocation due to a stress σ applied to a crystal is given by the Peach–Koehler equation

$$K = \sigma \mathbf{b} \times \mathbf{s} \quad [2a]$$

or the magnitude of the force K in the slip system due to the resolved shear stress τ

$$K = \tau b \quad [2b]$$

The imposed strain rate is reflected by the dislocation velocity through the Orowan equation

$$\dot{\epsilon} = \rho_m b v \quad [3]$$

where ρ_m is the density of the mobile dislocations moving with an average velocity v . The velocity, of course, depends on the applied stress σ . One can imagine the dislocations as rigid rods, moving with velocity v due to a force K , and this process is experienced macroscopically as a plastic deformation with strain rate $\dot{\epsilon}$ at a flow stress σ .

Twinning

While crystallographic glide by dislocation slip is the dominating deformation mechanism in metals, deformation twinning is also observed to accommodate a plastic strain, particularly at low temperatures in metals and many intermetallics. A deformation twin has an atomic arrangement that is the mirror image of the parent crystal. Due to the mirror symmetry, the crystallographic structure is conserved, but the crystal has a different shape (Figure 1c). The generation of a twin corresponds to a simple shear deformation by a displacement parallel to the twinning plane (mirror plane). In contrast to the dislocation glide, the shear strain γ is constant for a given crystal structure, for example, $\gamma = \sqrt{2}/2$ for cubic crystals. Twinning plane and displacement direction constitute a twin system in analogy to a slip system (Table 1).

Since for a given shear strain, the atomic displacement increases with growing distance from the twinning plane (Figure 1c), twins are usually thin, and their formation requires high stresses which are available only at low temperatures because the material strength increases with decreasing temperature. Deformation twinning is liable to occur if the flow stress is high and the twin boundary energy (approximately half of the stacking fault energy (SFE)) is low. The f.c.c. metals and alloys with low SFE undergo deformation twinning, such as silver at room temperature or copper at liquid nitrogen temperature. As the SFE decreases upon alloying, most alloys are prone to twinning during low-temperature deformation, for example, copper alloys, such as α brass (Cu–Zn) where twinning constitutes the major low-temperature deformation mechanism. Deformation twinning is most prominent in materials where dislocation slip cannot fully accommodate the imposed strain, for example, in h.c.p. metals and alloys with $c/a > 1.63$ owing to their low number of crystallographic slip systems. For an arbitrary deformation, a crystal needs to activate five independent slip systems to satisfy the five independent elements of the strain tensor. (A slip system of a set is independent, if its deformation cannot be accomplished by the other systems of the set.)

In h.c.p. metals with $c/a > 1.63$ (e.g., zinc), there is only slip on the basal plane and therefore, there are only two independent slip systems. This is sufficient to deform single crystals to very large strains. However, the individual grains of a polycrystal have to deform compatibly with the adjacent grains to avoid occurrence of holes or overlap. This can be accomplished only if the individual grains can undergo an arbitrary shape change at their boundaries, for which five independent slip systems are required. Therefore, polycrystals of zinc, for example, have to activate mechanical twinning for deformation. Owing to the high stresses and the less perfect adaptation to the shape change of neighboring grains in a polycrystal by twinning, the strain to fracture is smaller than in material deforming only by dislocation slip. Also, due to crystallographic effects, h.c.p. metals and alloys with $1.63 \leq c/a \leq 1.73$ cannot deform to a large degree by twinning, since twinning ceases to comply with the imposed shape change due to crystal reorientation and the fact that only one sense of twinning shear is crystallographically possible (the opposite shear $-\gamma$ does not generate a twin orientation). This is the reason why polycrystalline h.c.p. magnesium ($c/a = 1.63$) and its alloys are not ductile at ambient temperature. Note that hexagonal metals such as titanium, beryllium, or zirconium are very ductile even at low temperatures since their ratio $c/a < 1.63$, which favors nonbasal slip and thus, provides sufficient independent slip systems.

Deformation Microstructure

When gliding dislocations become immobile, they are stored in the crystal. The spatial distribution of these stored dislocations can occur at random or in distinct patterns. Most metals and alloys reveal nonstatistical dislocation distributions. Typically, dislocations arrange in cellular patterns, that is, in high dislocation density (cell) walls, which enclose volumes (cells) of considerably lower dislocation densities. For most commercial cold forming processes – such as rolling, the cellular arrangements are superimposed by deformation inhomogeneities, which typically have a band-like shape and can assume macroscopic dimensions to be recognized by the bare eye. In rolled materials, besides microscopic microbands, which appear like distinctly framed elongated dislocation cells under the microscope, there are two major types of deformation inhomogeneities namely, deformation bands and shear bands which can best be recognized in micrographs of the lateral surface. Deformation bands are elongated microstructural features that extend parallel to the rolling direction and that gradually accommodate a large misorientation to the matrix. Shear bands are deformation inhomogeneities, which extend under an angle of $30\text{--}35^\circ$ to the rolling direction. Copper-type shear bands comprise clusters of elongated cells, which are confined to grain dimensions. In contrast, brass-type shear bands have (macroscopic) dimensions comparable to the sample thickness. Their internal structure is composed of very small granular features, typically globular grains of nanometer size. The origin and structure of shear bands are far from being understood, but they are generally assumed to be due to local softening (like texture softening) or enforced macroscopic shear in case of obstructed dislocation glide. Brass-type shear bands occur typically in alloys with low SFE (e.g., alpha brass). Copper-type shear bands are formed during cold rolling of f.c.c. metals and alloys with higher SFE.

Hardening Behavior

The mechanical properties of a material are typically measured in a uniaxial tension test, where the force is recorded to elongate a cylindrical specimen at constant speed. The force F divided by the initial cross section q_0 defines the engineering stress, and the length change Δl divided by the original length l_0 defines the engineering strain. If force and elongation are normalized by the instantaneous cross section q or length of the specimen l , they are referred to as true stress and true strain, respectively. The hardening curve is the dependence of the true stress on true strain. The true stress at a given strain is called the flow stress.

The storage of dislocations during deformation leads to an increased glide resistance for moving dislocations which is experienced as an increased flow stress with increasing strain (Figure 2a). The rise of stress σ with strain ϵ , is referred to as strain hardening or work hardening, and the slope of the hardening curve $d\sigma/d\epsilon$ is the work-hardening coefficient or hardening rate. It is conventionally measured in uniaxial tension or compression tests. While the hardening curves of different materials or at deformation conditions vary considerably, there is a characteristic shape of the engineering stress–strain curve, namely after yielding a curve with a single maximum, although the strength level and hardening rate can be very different.

Of particular interest for forming processes is the hardening behavior for large strain deformation, for example, sheet rolling. A typical true stress–strain behavior for large strain deformation exhibits, after yielding, some transient with high but decreasing hardening rate until a low but constant rate is attained (Figure 2b), that is, the stress increases linearly with strain, and eventually a steady state (constant flow stress) is attained. Correspondingly, the large strain-hardening curve exhibits five distinct stages:

1. Right after yielding, transition to athermal hardening (observed only in single crystals oriented for single slip);
2. Athermal hardening with constant high hardening rate $d\sigma/d\epsilon \approx G/30$ (extended range only in single crystals at low temperatures);
3. Dynamic recovery range, hardening rate decreasing linearly with stress;
4. Large strain hardening with constant low hardening rate; and
5. Transition to steady state or unstable microstructure, usually not attained during cold deformation.

The important stages of the flow curves of commercial metals and alloys for industrial forming processes are stages 3 and 4. Their extent and level depends on material composition and processing and, thus, is history dependent! The hardening behavior reflects the glide resistance of the moving dislocations and, therefore, depends on the dislocation structure S , which is strongly dependent on processing history, that is, at strain rate $\dot{\epsilon}$ and temperature T :

Figure 2 (a) True stress–true strain curve of an Al–1%Mn alloy (AA3103), measured at 300°C and a constant true strain rate of 0.1 s^{-1} ; (b) $d\sigma/d\varepsilon$ vs. σ .

$$\sigma = \sigma(\dot{\varepsilon}, T, S) \quad [4]$$

For this particular reason, the macroscopic strain is not a state parameter and, therefore, a prediction of flow stress as an empirical function of strain $\sigma(\varepsilon)$ is physically wrong although, due to simplicity, it has been a longstanding engineering practice.

Texture

A simple shear deformation is always accompanied by a rigid-body rotation, because the displacement gradient tensor is not symmetrical. Since plastic deformation in metallic materials proceeds by simple shear mechanisms (dislocation glide, mechanical twinning), the grains in a polycrystal change their crystallographic orientation during deformation – except for a few orientations which are stable under the imposed deformation conditions – and rotate toward the stable orientations. For a given forming process, such as rolling, wire drawing, or extrusion typical orientation distributions, that is, crystallographic textures develop, depending on deformation mechanism. An orientation distribution is most adequately represented in orientation space, where each orientation is represented by one point. The orientation distribution after large strain deformation is confined to a small volume in orientation space. For instance, the rolling texture of f.c.c. materials appears like a tube in orientation space (Figure 3) and can essentially be understood as consisting of only a few (ideal) orientations with some scatter. Crystallographic textures cause anisotropic mechanical properties, which make themselves felt during thermomechanical processing, metal forming, and in-service behavior.

Softening: Recovery and Recrystallization

During plastic deformation, dislocations are introduced to accommodate the imposed shape change. Dislocations, however, are crystal defects which are not stable in thermodynamic equilibrium; thus, the crystal strives to remove them. At low temperatures, the dislocation arrangement is in mechanical equilibrium and, therefore, stable. At elevated temperatures, however, thermally activated processes destabilize the dislocation structure and substantially change or even remove the deformation-induced microstructure which drastically affects microstructure, texture, and mechanical properties (Figure 4). There are two major restoration processes: recovery and recrystallization. They are termed static processes if they occur subsequent to deformation during annealing, or are referred to as dynamic recovery and dynamic recrystallization if they proceed during deformation. Dynamic recovery is also strain

Figure 3 Rolling texture of pure copper: three-dimensional representation in orientation (Euler) space, $\{111\}$ polefigure.

Figure 4 The effect of cold forming and annealing on the properties of a Cu-35%Zn alloy.

induced and is, therefore, an integral part of the strain-hardening process at any temperature. Dynamic recrystallization is an important phenomenon during hot working (see below) and liable to occur for $T > 0.5T_m$ (T_m – melting temperature). While recovery essentially consists of a dislocation rearrangement in the as-deformed structure, a completely new microstructure is formed atom by atom during recrystallization. Recrystallization proceeds by nucleation of virtually dislocation-free grains, which grow at the expense of the deformed matrix. The moving grain boundaries of the expanding nuclei are capable of absorbing the deformation-induced dislocations so that finally an almost dislocation-free granular structure is generated. Typical dislocation densities of recrystallized polycrystals are 10^{10} m^{-2} compared to up to 10^{16} m^{-2} for heavily deformed materials.

Recovery and recrystallization have different kinetics and different impact on properties. Invariably either process causes a softening of the material, and fully recovered and fully recrystallized materials have comparable yield stresses. The texture development is very different, however. The deformation texture is essentially retained during recovery or slightly increased in sharpness. During recrystallization, a completely new and different texture is generated. The recrystallization texture can be very sharp, like the cube texture in rolled and annealed aluminum, which gives rise to strong anisotropy during subsequent forming of the sheet. Typically, specific types of deformation textures, as shown in Figure 3 for rolling, transform to specific recrystallization textures in f.c.c. and b.c.c. materials. However, small changes in chemical composition or processing history can totally alter the recrystallization texture, even if the deformation texture appears unchanged. Advanced codes for recrystallization structure and

Figure 5 (a) Stress–strain curves of dynamically recrystallizing material (alloy 800 H); (b) the first recrystallized grains form predominantly at grain boundaries (necklace structure in Ni_3Al).

texture prediction with high spatial and temporal resolution (e.g., cellular automata or Monte Carlo simulation approaches) are now available which can be interfaced to FEM or superimposed to real deformation microstructures to account for spatial variation of the microstructure.

At temperatures above $0.5T_m$, recrystallization can also occur concurrently with deformation. This is referred to as dynamic recrystallization and makes itself felt by either a single-peak or multiple-peak flow stress behavior. A typical flow curve of a dynamically recrystallizing material and its associated microstructure are shown in Figure 5. Dynamic recrystallization typically occurs during the hot working of low SFE materials. Important examples are austenitic steels and copper alloys. It limits the flow stress and therefore, keeps hot working forces low and at the same time, it improves ductility (strain to fracture). The dynamically recrystallized grain size depends only on the flow stress and thus can be controlled by the strain rate and deformation temperature.

Modeling

For engineering practice, the mechanical behavior of materials must be known (e.g., the hardening curve). Most commonly, it is measured and fit to empirical functions. These functions, however, do not have any predictive power and cannot be used beyond the tested limits. For predictions of mechanical properties with the change of materials chemistry or processing conditions, microstructural models have to be used, since microstructure defines the state variables of materials properties.

Advanced work-hardening models are based on the dislocation theory. These models can either be statistical dislocation density-based models or dislocation dynamic models (Figure 6a). Statistical models follow a common scheme, namely, the formulation of a structure evolution equation ($d\rho/d\varepsilon$) and a kinetic equation of state ($\sigma = f(\rho, T, \dot{\varepsilon})$) to relate the structure with the glide resistance. These relations are formulated as differential equations and hence can account for the transient microstructure evolution. The total change of dislocation density $d\rho$ in a strain increment $d\varepsilon$ reflects the structure evolution due to production of dislocations $d\rho^+$ and dynamic recovery (e.g., annihilation, dipole formation, lock formation) $d\rho^-$:

Figure 6 Deformation microstructure: (a) generated by two-dimensional dislocation dynamics; (b) observed in pure aluminum, cold rolled to a strain of 0.1. (Modified from Liu *et al.* (1998) Effect of grain orientation on deformation structure in cold rolled polycrystalline aluminum. *Acta Materialia* 46: 5819–5838, with permission from Elsevier.)

$$d\rho = d\rho^+ - d\rho^- = (f_1 - f_2)d\varepsilon \quad [5]$$

The functions f_1 and f_2 have to be determined from the dislocation theory. They depend on the particular processes considered, and their actual values vary with the dislocation structure. The major problem is a proper incorporation of dislocation patterning in the theory. It is a common conception that the dislocations are arranged in a cell structure (Figure 6b), but different approaches have been proposed for the dominant stress and strain rate controlling processes. Due to the nonhomogeneous dislocation distribution, the flow stress will be a volume (V) weighted average of the flow stress in cell walls σ_w and cell interiors σ_i

$$\sigma = \sigma_w V_w + \sigma_i V_i \quad [6]$$

In a dislocation dynamics model, the dislocations are modeled as line defects in a continuum and represented by their stress field. Since the continuum theory of dislocations is well established, the equations of motion can be formulated and the dislocation arrangement can be calculated from eqns [2] and [3]. However, the fundamental approach and the applicability to arbitrary deformation conditions have to be paid for by a substantial investment in computer power and computation time.

Owing to the long-range stress fields and the self-interaction of curved dislocations in three-dimensional dislocation dynamics, the problem becomes intractable for today's and tomorrow's high-power computers. Simulations with two-dimensional geometry are possible and have been performed but can only be applied to problems of two-dimensional geometry such as thin films. For bulk deformation, two-dimensional dislocation dynamics are of limited use.

Applications

Plasticity is the main prerequisite for metal forming, for example, rolling, forging, wire drawing, to produce semi-finished products and for the final shaping of parts, for example, by sheet forming. The excellent formability of metals is one of the reasons for their extensive industrial use. During the classical processing route of a metallic part, from the liquid state to the finished product, the material undergoes multiple deformation and heat treatment cycles. For example, consider the fabrication of an aluminum (or steel) can from a sheet (Figure 7).

After casting and homogenization the material is hot rolled, cold rolled, and annealed before the final part is produced from the sheet by deep drawing. While the material undergoes a shape change and experiences work hardening during rolling, it softens

Figure 7 Production chain for sheet-forming process.

during interstand times and during back annealing. Since the microstructure changes during each processing step and as the microstructure determines the properties of the final part, processing has to be fine-tuned to meet terminal material specifications. These processes and the respective microstructural evolution can now be simulated by advanced computer codes.

Nomenclature

b	Burger's vector magnitude (length)
c	concentration of solute (atomic fraction)
d	grain size (length)
L	spacing between obstacles (length)
r	average particle radius (length)
T_m	melting temperature (K)
v_f	volume fraction of particles
α	dimensionless constant for work hardening
β	dimensionless constant for solid solution strengthening
γ	dimensionless constant for particle strengthening
$\Delta\tau$	additional strength increment (force/area)
κ	constant for grain-boundary strengthening ($\text{length}^{1/2}$)
λ	interparticle spacing (length)
μ	shear modulus (force/area)
ρ	dislocation density (length^{-2})
σ	stress (force/area)

Introduction

The strength of metallic materials depends in considerable detail upon the structure at many length scales, from the fundamental atomic interactions at $\sim 10^{-10}$ m to interaction among macroscopic structural components as large as $\sim 10^{-3}$ m. The mechanisms responsible for strengthening metals have been the subject of considerable study for many decades, and are relatively well understood for traditional microstructural length scales. At low temperatures, the strength of crystalline metals is in large part governed by the interaction of dislocations with one another and with other features of the microstructure. Therefore, the main focus of this article is on these interactions, and the general scaling laws that relate these microscopic processes with macroscopic measurements of strength. In metals with microstructural components large enough to be regarded as continua, additional strength can be derived by sharing of the applied load between phases, which is discussed briefly. Finally, the limitations of these various strengthening mechanisms are discussed for cases where the temperature is high or the characteristic microstructural length scale is very fine.

Low-Temperature Dislocation-Based Strengthening Mechanisms

In crystalline metals, strength and other mechanical properties are governed by the prevalence and mobility of defects in the crystal structure. At low temperatures (i.e., below about one-third of the melting point), the most important defects in this regard are dislocations, which can be regarded as the “carriers” of plastic strain. Hence, the primary goal of most forms of metal strengthening is to regulate the movement of dislocations, which is generally accomplished through the introduction of obstacles. The four main

strengthening mechanisms at ambient temperature, that is, work hardening, solid solution strengthening, particle hardening, and grain-boundary strengthening, are all variations upon this theme. Each of these mechanisms has been studied and modeled in considerable detail, and the reader is referred to the “Further reading” section for more exhaustive discussions. Here these concepts are explored within the framework of a relatively general scaling law that predicts the shear strength increment $\Delta\tau$ gained by incorporating obstacles of spacing L in the structure:

$$\delta\tau \propto \frac{1}{L} \quad [1]$$

This additional stress is required to allow dislocations to bypass the obstacles, and the proportionality constant depends in large part upon whether dislocations can cut through the obstacles (“soft” obstacles), or must bypass them by bowing (“hard” obstacles).

In what follows, how eqn [1] applies for the important mechanisms listed above is discussed broadly, assuming pure metals or dilute alloys, and neglecting details such as the crystallography of defects or the underlying crystal structure of the base metal. Furthermore, the homogeneous nucleation of dislocations is not considered to contribute to strength, since most engineering metals and alloys already contain an appreciable density of dislocations ($\sim 10^{10}$ – 10^{14} m $^{-2}$) prior to plastic flow.

Work Hardening

The principle underlying work hardening is that plastic flow induces structural changes which make subsequent plastic flow ever more difficult; the more it is deformed, the stronger a metal becomes. During plastic flow of a polycrystalline metal, work is dissipated by the motion and interaction of dislocations. Strain energy is stored through a net increase in dislocation line length through processes such as bowing around various obstacles and pinning points, and the sequential emission of new dislocations from, for example, Frank–Read sources.

As dislocations entangle, they can form sessile kinks or jogs which act as pinning points along the dislocation line, such that the obstacle spacing L is proportional to $\rho^{-1/2}$, with ρ the dislocation density. When this scaling is introduced into eqn [1], it yields the classical parabolic-hardening law used widely for polycrystalline metals:

$$\delta\tau = \alpha\mu b\sqrt{\rho} \quad [2]$$

where the constants α , μ , and b have now been introduced. In this formulation μ is the shear modulus, b is the magnitude of the Burger’s vector, and α is a temperature-dependent proportionality constant ~ 0.2 – 1 in the athermal limit.

Equation [2] has been experimentally validated for many metals; an example of data compiled for copper is shown in Figure 1. Perhaps counter-intuitively, the nature of the dislocation distribution does not affect the general relevance of eqn [2]. For example, in some materials dislocations self-assemble into inhomogeneous spatial configurations. In such cases, it is possible to parametrize, for example, the average dislocation cell size, and use it to produce additional scaling laws; these ultimately reduce to either eqn [2] or other very similar relationships.

Although eqn [2] is surprisingly general in its applicability, it is important to note that $\Delta\tau$ from work hardening is fundamentally limited by the maximum value of ρ that can be sustained in a given metal. With large amounts of plastic strain, the dislocation

Figure 1 Data relating the shear strength of copper (normalized by the shear modulus μ) to the square root of dislocation density (normalized by the Burger’s vector magnitude). The dislocation density has been obtained by chemical etching and optical microscopy on planar cross sections. (Data from Mecking H and Kocks UF (1981) Kinetics of flow and strain hardening. *Acta Metallurgica* 29: 1865–1875.)

density can increase by orders of magnitude before saturating at a temperature- and material-dependent value as high as 10^{16} m^{-2} . This saturation is a consequence of “dynamic recovery,” wherein the production of new dislocation line length is offset by annihilation processes which become more active with increasing dislocation density. Nonetheless, strain hardening can increase a metal’s strength by orders of magnitude compared with the stress required to move an isolated dislocation.

A topic of current research interest is the effect of nonuniform deformation on strain-hardening behavior, in which plastic strain gradients are necessitated by the test or microstructural geometry. Plastic strain gradients require the presence of “geometrically necessary” dislocations to accommodate them, so it has been speculated that higher total dislocation densities will result whenever such gradients exist. These effects become increasingly important at fine length scales, for example, in very small specimens or thin films, nanoindentation experiments, or for metals with fine scale microstructural features; in these cases, the strain gradients resulting from nonuniform deformation are steeper owing to the reduced dimensionality. In general, strain gradient effects are believed to occur in metals at length scales below $\sim 100 \mu\text{m}$.

Solid Solution Strengthening

For pure metals, the addition of a low concentration of a second component in solution can provide soft barriers to the motion of dislocations through the crystal. Solutes interact with dislocations through two main effects. First, solute atoms change the local values of elastic constants, which in turn change the line energy of a dislocation. Solute atoms which stiffen the matrix repel dislocations, while those which make the matrix more compliant attract them. Second, solute atoms added to a pure metal create distortions in the crystalline lattice, and the associated stress fields can interact with dislocations; again the interaction can be either attractive or repulsive, depending upon the size mismatch of the solute atoms with respect to the matrix and their position with respect to the dislocation core. Whether the solutes repel or attract dislocations, the net result is strengthening, as additional stress is required to force a dislocation to approach or depart, respectively, the vicinity of a solute atom.

Within a slip plane, the density of solute atoms is given by their concentration, c , and the spacing between solutes goes as $b \times c^{-1/2}$. Therefore, eqn [1] takes a parabolic form with respect to concentration:

$$\delta\tau = \beta\mu b \frac{\sqrt{c}}{b} \quad [3]$$

where the proportionality constant β depends upon how strongly the solute atoms interact with dislocations. In the case of substitutional alloying additions, the stress field around solute atoms is approximately spherical, which leads to rather mild interactions and values of β much less than unity. For some crystal symmetries, the strain field associated with an interstitial solute can be nonspherical, providing much harder obstacles to dislocation motion, and values of β near unity. A common important example in this regard is the interstitial sites in a body-centered cubic lattice, where the distortion accompanying a solute is tetragonal. Models are available to predict β with reasonable accuracy in each of these cases. Figure 2 shows some classical data sets for substitutional and interstitial alloying, where the parabolic form of eqn [3] is validated and the relative strengths of the two obstacle types are apparent.

Particle Strengthening

In the same vein as solid solution atoms, fine dispersed particles can also serve as dislocation pinning points. When second-phase particles are present by virtue of nucleation and growth processes, the metal is said to be “precipitation strengthened,” whereas the extrinsic incorporation of fine particles is generally referred to as “dispersion strengthening.” In the simplest case these particles can be assumed to be “hard” obstacles to dislocation motion, and their strengthening effect is based upon the spacing of the particles, L . Unlike solute atoms or dislocation locks, particles have finite sizes that can be of similar order to the interparticle spacing, λ .

Figure 2 Classic examples of the concentration dependence of the solid solution strength increment $\Delta\tau$. Solutes with symmetric strain fields such as the substitutional case of Cu dissolved in Al ($\square$) generally have a modest strengthening effect, while asymmetric strain fields associated with, for example, interstitial C in Fe ($\bullet$) or N in Nb ($\circ$) produce more significant strengthening. (Data are from Wert CA (1950) *Journal of Metals* 188: 1242–1244, Evans PRV (1962) *Journal of the Less-Common Metals* 4: 78–91, and Koppenaal TJ and Fine ME (1962) *Transactions of the Metallurgical Society of AIME* 224: 347–353.)

Therefore, the effective obstacle spacing is given by $L \approx (\lambda - 2r)$, where r is the average radius of the particles. For small particles, the spacing of obstacles in the slip plane of a dislocation goes roughly as $v_f^{1/2} r^{-1}$, so the familiar parabolic strengthening law is recovered using eqn [1]:

$$\delta\tau = \gamma\mu b \frac{\sqrt{v_f}}{r} \quad [4]$$

The proportionality constant γ is close to unity for hard particles, for example, for dispersed ceramic particulates or very large precipitated particles in a metallic matrix.

In many cases the particulate obstacles are, at least in principle, capable of being sheared by the passage of a dislocation. In these cases, the obstacles are said to be “soft,” and the energy penalty associated with shearing them is the source of strengthening. Some notable examples by which such soft obstacles can promote strengthening are as follows:

1. Coherent particles with a lattice parameter mismatch to the matrix phase create strain fields that interact with dislocations in a manner similar to that described above for solid solution strengthening.
2. The shearing of particles creates additional interfacial area and thereby increases the total interfacial energy of the system.
3. In “order strengthening,” an incident dislocation creates an antiphase boundary (with an attendant interfacial energy term) in a chemically ordered particle.
4. The difference in elastic modulus between particle and matrix changes the dislocation energy as it traverses the particle, providing an obstacle to either its entrance or exit from the particle.

All of these “soft” obstacle strengthening mechanisms, as well as some more obscure ones, tend to obey the scaling law of eqn [4], with different scaling parameters γ that can also be functions of the particle size r . However, it should be noted that some derivations for case (2) can yield a linear volume fraction dependence.

Apart from the volume fraction dependence of particle strengthening described in detail above, the absolute magnitude of the average particle dimension also has a measurable impact on the strength required to pass a dislocation. Larger average particle sizes promote strengthening by creating “harder” obstacles, because a passing dislocation must traverse a larger area of precipitate, requiring more energy via mechanisms (2) and (3) above, while the stress field of a coherent particle also increases with size and enhances strength via mechanism (1). However, a larger average particle size necessitates a proportionally wider interparticle spacing if their volume fraction is held constant; this effect leads to a weakening via eqn [1]. Therefore, for a constant v_f , increasing the average particle size gives rise to a “cutting-to-bowing” transition, with the material strength first increasing and then decreasing with average particle size. These two regimes correspond to shearing of soft obstacles for small particle sizes (cutting), and pinning of dislocations at hard obstacles for larger particle sizes (bowing). An example of such a transition is shown for the technologically relevant nickel–aluminum system in Figure 3, in which the particles are precipitates of the Ni_3Al phase.

Figure 3 The strengthening of Ni due to the presence of a constant volume fraction dispersion of fine Ni_3Al precipitates with a given average radius. Over the range of radii < 10 nm, increasing the precipitate size promotes strengthening, but beyond this range causes weakening. These regimes correspond to the “cutting” and “bowing” mechanisms, respectively. (Data from Brown LM and Ham RK (1971) Dislocation–particle interactions. In: Kelly A and Nicholson RB (eds.) *Strengthening Methods in Crystals*, pp. 12–135. London: Applied Science Publishers.)

Grain-Boundary Strengthening

Because the adjacent crystals at a grain boundary have a misorientation between both the slip plane traces and the slip directions, dislocations cannot, in general, transmit through grain boundaries without an additional increment of applied strain energy. For more extreme misorientations, the stress required for transmission can be higher than that required to activate a new dislocation source in the adjacent grain. In either case, dislocations on a common slip plane in the first grain tend to pile up at the grain boundary, until the stress at the head of the pileup becomes large enough to activate slip in the second grain. In this manner, grain boundaries present very “hard” obstacles to dislocation motion, but they are not point obstacles in the same vein as solute atoms or particles. Therefore, the scaling law of eqn [1] does not simply apply to the case of boundary strengthening, although a similar parabolic hardening law does emerge from analysis of the slip transmission problem:

$$\delta\tau = \kappa \frac{1}{\sqrt{d}} \quad [5]$$

where d is the average grain size of the metal and κ is a material-specific constant with units of $(\text{length})^{1/2}$; eqn [5] is commonly referred to as the Hall–Petch relationship.

In Figure 4 the hardness, which is linearly proportional to strength, is plotted for pure Ni as a function of the reciprocal square root of grain size. The data from multiple authors indicate that the strength increases linearly with $d^{-1/2}$, and eqn [5] holds over orders of magnitude in grain size, from hundreds of microns in standard engineering materials down into the increasingly important nanocrystalline regime. As evidenced by the conformity of the data from various authors working on different specimens, eqn [5] is quite robust. Potentially complicating issues such as distributions of grain size or grain-boundary misorientation tend to be subsidiary to the scaling law of eqn [5], and are subsumed in the constant κ . Far stronger variations are observed from one material to another, most particularly depending on the number of slip systems available.

A current topic of particular interest in the area of grain-boundary strengthening is the validity of the Hall–Petch relationship at grain sizes in the nanometer range, where extreme strength has been reported. However, at a grain size of zero, the Hall–Petch relationship would predict an unphysical infinite strength, so it has been widely speculated that eqn [5] will break down at nanometer length scales. Recent experimental and computational work has supported this speculation, including the experimental data for nickel shown in Figure 4 below ~ 12 nm. This breakdown is associated with the activation of deformation mechanisms normally associated with high temperature, as will be discussed in more detail in a later section.

Low-Temperature Continuum-Level Strengthening

On a coarser structural scale, it is possible to strengthen a base metal by adding a second phase that can bear a disproportionate fraction of the load. This is often desirable when the base metal has properties critical to the application, such as low density, high

Figure 4 A typical “Hall–Petch” plot showing the hardness (which is proportional to the yield stress) of nickel as a function of the reciprocal square-root grain size, d . (Data are collected in Schuh CA *et al.* (2002) *Scripta Materialia* 46: 735–740, from various other sources.)

ductility, conductivity, or corrosion resistance, but lacks sufficient mechanical strength. The concept of load sharing is the basis of many technological structural materials from reinforced concrete to advanced polymeric composites. In the area of metallurgy, load sharing operates in microstructures with second phases formed *in situ*, such as steels containing coarse iron carbide or martensite phases, as well as in metal–matrix composites such as SiC-reinforced aluminum.

The load-sharing mechanism arises completely due to mismatch between the mechanical properties of the constituent phases, and, from a mechanistic perspective, can be regarded as independent of microscale mechanisms; dislocation interactions with coarse second phases are less important than the global transfer of load that results from such interactions. Accordingly, continuum mechanical approaches are generally used to derive the strengthening effect from load transfer. If the two phases or components of the microstructure are initially deformed only elastically, then the only variable controlling the strength of the dual-phase structure is the fraction of the applied stress that is carried by each. The total applied stress σ partitions such that the average stress carried by each phase (σ_1 and σ_2 for phase “1” and “2,” respectively) obeys

$$\sigma = \sigma_1(1-\nu_f) + \sigma_2\nu_f \quad [6]$$

where ν_f is the volume fraction of phase 2. Although this rule is generally true for any dual-phase structure when the stresses are averaged over the volume of the material, eqn [6] is not always useful to predict, for example, yield strength. This is because the local values of stress may be significantly concentrated, leading to local yielding in one of the phases. Despite this limitation, eqn [6] illustrates the basic principle of load transfer, where a stronger phase can relieve the stress borne by the weaker, giving a strength intermediate between the two components. Accurate predictions of yield and fracture strengths for dual-phase materials are dependent on the details of the composite geometry, for which a vast literature exists. The reader is referred to the “Further reading” section for more detailed treatments of specific cases.

Limitations of Strengthening Mechanisms due to Thermal Activation

The strengthening mechanisms described above can all be understood on an athermal basis, and are best applied in the limit where diffusional rearrangement of matter is slow. When dislocation motion and diffusion have similar timescales, for example, at high temperatures, the above scaling laws no longer strictly apply. In these cases, new physics are required to accurately predict the strength and rheology of metals. Although it is beyond the scope of this article to treat diffusive deformation mechanisms in detail, it is important to appreciate the limitations on the mechanisms described above for cases in which (1) bulk diffusion and (2) interfacial or grain-boundary diffusion are active at the deformation temperature.

Bulk Diffusion Effects

For many of the strengthening mechanisms described above, the motion of dislocations (particularly those of edge character) is considered to be restricted to a plane. However, the climb of edge dislocations out of their slip plane can occur by the absorption or emission of vacancies at the dislocation core. In many cases, this enables an additional means for obstacle bypass, albeit one that is rate-limited by the diffusive flow of vacancies to (or from) the dislocation core. The supply of vacancies needed to enable dislocation climb can flow either through the bulk, which generally requires temperatures above about two-thirds of the melting temperature, T_m , or along the core of the dislocation itself, which can be significant at somewhat lower temperatures above about $T_m/3$.

For solid-solution strengthened materials, diffusion can also lead to mobility of the obstacles themselves. In cases where there is an attractive interaction between solute atoms and dislocations, there is a tendency for these features to move in tandem. For example, at temperatures where the solute mobility is high, the motion of dislocations becomes a viscous process as the solute atoms follow the moving dislocation. At somewhat lower temperatures, the phenomenon known as “strain-aging” can occur, whereby plastic deformation initially detaches dislocations from solute pinning points, but extended time or thermal exposure can allow solutes to redistribute and again pin the dislocations. For substitutional solid solutions, the solute can be regarded as essentially immobile at temperatures below approximately $T_m/2$, while for interstitial solid solutions this limit can be considerably lower, down even to ambient temperature.

In multiphase microstructures, high temperatures or long durations can also lead to evolution of the size and spacing of precipitated obstacles. During this so-called “coarsening” process, the volume fraction of precipitate phase remains constant while the average precipitate size increases linearly with the cube root of time. As described above, a limited amount of such particle growth can be beneficial, but the maximum strength associated with the cutting-to-bowing transition generally occurs at very fine precipitate sizes, such that microstructural coarsening usually leads to weakening. This issue is sometimes suppressed in practice through the addition of slow diffusing elements that decelerate coarsening. Finally, coarsening is not usually an issue for dispersion-strengthened materials, which employ particles with low solubility and/or diffusivity in the matrix.

Inter crystalline Diffusion Effects

Additional time-dependent deformation mechanisms are associated with the diffusive rearrangement of atoms in intercrystalline regions such as grain and phase boundaries or triple junctions. For example, it is possible for strain to be accommodated solely by the diffusional flow of atoms along grain boundaries, from interfaces under net compression to those in net tension. For fine microstructures, grains can even become mobile relative to one another through the operation of viscous “grain-boundary sliding” and stress-induced grain rotations. Although these mechanisms do not directly influence all of the dislocation-based strengthening mechanisms described earlier, they can negate the expected scaling laws set forth above when they operate at a lower stress level than the athermal mechanisms. For example, the Hall–Petch scaling law that describes grain-boundary strengthening is known to fail at high temperatures, where finer grains actually promote weakening due to the dominance of diffusive deformation mechanisms. For these reasons it is common to develop coarse microstructures or even single crystals for high-temperature structural metals. Continuum-level load sharing can also be frustrated by interfacial diffusion and sliding between phases in a composite structure, increasing the fraction of load borne by the weaker matrix phase.

Because interfaces tend to have excess free volume, they also represent “short-circuit” diffusion paths that are more easily activated, and therefore intercrystalline diffusion can become significant at even lower temperatures than bulk diffusion. Additionally, since the net amount of matter that can be transported along interfaces scales with the interface density, these processes are also accelerated in microstructures of fine scale. For example, it is presumed that the high density of crystalline interfaces in nanocrystalline materials leads to diffusional deformation mechanisms even at room temperature, again leading to the breakdown of the Hall–Petch boundary strengthening law.

EDITOR-IN-CHIEF BIOGRAPHY

Tapash Chakraborty is a retired professor of physics from the University of Manitoba, Canada, where he was also the Canada Research Chair in Nanoscale Physics (2003–17). His research focus has been on many-body theories of various quantum materials, such as nuclear matter, helium liquids, and electron-hole liquids, that he studied under the tutelage of late Professor Manfred Ristig, at the University of Köln (1979–81). Just a year after the discovery of the fractional quantum Hall effect, he (working with his coworkers) demonstrated that electron–electron interactions could actually lead to quantum Hall states with nontrivial spin configurations, and that the low-lying excitations could be described as “spin-reversed quasiparticles.” This prediction motivated much experimental work from laboratories around the world, as a result of which the concept of spin-reversed quasi-particles was established.

Similarly, his work on the quantum Hall states in double layer systems has received much attention from the community. Furthermore, Dr. Chakraborty (working with Dr. P. Maksym and others) made pioneering contributions to the many-electron theory of quantum dots. Dr. Chakraborty has also contributed to the theory of electronic properties of various nanoscale systems, such as spin-orbit coupled quantum dots, quantum rings, and single- and double-layer graphene (primarily with Dr. V. Apalkov). He has authored many books and reviews: the book with Dr. Pietiläinen on the quantum Hall effect and the single-authored book on quantum dots have become standard references in their respective fields.

INTRODUCTION

Electrons in orbits contained by the quantum,
And atoms conjoined by the dipolar force,
Gravity balanced by pressure
And flap of a wing.
Here, I remember the angles and curves,
Calculus, I learned it all –
Each bird bit and moon fracture
Fixed by the symmetries,
Airborne and airless, aloft.

– Alan Lightman: *Song of Two Worlds*

Condensed matter physics (CMP) is the largest discipline in physics, involving a wide variety of interesting concepts and challenges. To quote [Leggett \(1992\)](#), CMP embraces topics “as diverse as traditional solid-state physics, neutron stars and the physics of biological matter.” He further added that, by a liberal definition “just about all of physics outside atomic, nuclear and particle physics and cosmology” fall in this vast enterprise¹. One of the primary goals of CMP is to explore the fundamental properties of matter—solids, liquids or gasses—comprising a large number of *interacting* constituent particles ([Laughlin and Pines, 2000](#)). The quantum-mechanical nature of these many-body systems makes condensed-matter highly nontrivial, sometimes counterintuitive and even astonishing. Superconductivity and the fractional quantum Hall effect (FQHE) naturally fall within that category. In fact, for the past four decades, the quantum Hall effects (QHEs) have been the epitome of elegant CMP ([von Klitzing et al., 2020](#)). Our fundamental system of units has been redefined following the discovery of the QHE when the “von Klitzing constant” $R_K = 25,812.8074593045 \, \Omega$ came into being ([von Klitzing, 2019](#); [Nawrocki, 2019](#)). Observation of the QHE in graphene² was crucial in determining the Dirac nature of charge carriers there (see for example, [Jiang et al., 2007](#)).

Another effect that outwardly resembles the QHE but is conceptually quite different is the FQHE, which is a quintessential manifestation of electron correlations governed by the Coulomb interaction ([Störmer, 1992](#); [Eisenstein and Stormer, 1990](#)). To explain this fascinating effect, [Laughlin \(1983\)](#) introduced his eponymous wave function that not only provided the foundation for understanding the effect but also triggered a new wave of ideas with impact far beyond the realm of CMP³. Who would have imagined that a large collection of interacting electrons confined on a plane in a perpendicular magnetic field would result in elementary excitations (quasiholes and quasiparticles) ([Chakraborty and Pietiläinen, 1988, 1995](#); [Halperin, 1983](#); [Clark and Maksym, 1989](#)) carrying fractional electron charge and obeying the exotic exchange statistics of anyons ([Halperin, 1984](#); [Arovas et al., 1984](#))? These quasiparticles and quasiholes of the Laughlin state still remain an enigma ([Laughlin, 1984](#); [Chakraborty, 1985](#); [Morf and Halperin, 1986](#)). Fractional statistics is a truly path-breaking concept in CMP that was introduced by [Leinaas and Myrheim \(1977\)](#), and has been recently confirmed experimentally ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

Much of the history of CMP can be viewed as a series of paradigm shifts⁴. The field evolved rapidly through frequent ground-breaking discoveries that challenged existing paradigms and opened up new applications, and this evolution is expected to continue ([Leggett, 2018](#); [Cohen, 2008](#)). For example, our current understanding of

¹Interestingly, some similarities do exist between the mathematical frameworks that describe low-temperature CMP and early-universe cosmology. See [Kibble and Srivastava \(2013\)](#).

²An isolated single layer of graphite consisting of carbon atoms bonded together in a hexagonal structure. See, e.g., [Abergel et al. \(2010\)](#).

³For example, an important aspect of Laughlin's theory is its seamless concinnity of classical plasma physics and the planar electron gas that has inspired others to use a similar approach to quark-gluon plasma ([Lu, 2022](#)).

⁴A detailed exposition of the meaning and examples of “paradigm shifts” (Kuhn-type) can be found in [Leggett \(2018\)](#).

the FQHE required deep mathematical analysis and a wide range of experimental exploration, which revealed a treasure trove of unique phenomena that are yet to be fully understood or explained. Other studies of electron correlations in low spatial dimensions have ushered in many groundbreaking notions, such as Pfaffian states, Majorana fermions in condensed matter, Chern insulators, and topological quantum materials that promise a fault tolerant means to perform quantum computation. The presence of incompressible FQHE states in monolayer graphene (Apalkov and Chakraborty, 2006), bilayer graphene (Apalkov and Chakraborty, 2010, 2011), and double-layer graphene (Liu et al., 2019) has demonstrated the robustness of the effect, and provides invaluable insight into the nature of this effect.

The dynamics of an electron in a periodic potential subjected to a perpendicular magnetic field has been an intriguing problem for more than half a century (Obermair and Wannier, 1976; Osadchy and Avron, 2001)⁵. Within the nearest neighbor tight-binding description of the periodic potential the electron energy spectrum is described by the Harper equation (Harper, 1955). Numerical solution of this equation (Hofstadter, 1976) has revealed that the applied field splits the Bloch bands into subbands and gaps. As the field is varied, the splitting of band continues indefinitely, leading to bands within bands within bands. When plotted as a function of the magnetic flux per lattice cell, the energy spectrum depicts a *fractal* pattern (a self-similar pattern that repeats at every scale) and is known in the literature as Hofstadter's butterfly because of the resemblance of the pattern to butterflies⁶. Observation of the butterfly spectra in real systems is an arduous task. For example, in ordinary crystalline lattices, the required magnetic field to see the butterflies exceeds 1000 Tesla, which is far beyond the reach of present-day technology. Graphene seems to be the ideal system in the quest of those fractal butterflies (Weiss, 2013). It is interesting to note that a mathematical solution of the Harper equation, in contrast to the numerical solution mentioned above, remained a challenging problem (the so-called Ten Martini Problem) for mathematicians until it was solved (Avila and Jitomirskaya, 2006) in 2006.

Magnetism has been known to mankind since ancient times, and it remains a major topic in CMP. The road to understanding magnetism has been long and tortuous. At various times in history, magnets were claimed to have the healing power to cure a myriad of ailments that included epilepsy, arthritis, gout, and baldness. Magnets were the prime ingredients for the "elixir of life" by Paracelsus (1493–1541). Then there was the healing process of "animal magnetism" proposed by Franz Anton Mesmer (1734–1815) (mesmerism)⁷, which was famously mocked in Mozart's *Così fan tutte* (Stephoe, 1986). Our current understanding of magnetism is deeply rooted in quantum mechanics as Van Vleck explained (Van Vleck, 1978): "Quantum mechanics is the key to understand magnetism. When one enters the first room with this key there are unexpected rooms beyond, but it is always the master key that unlocks each door." For centuries, the magnetism of certain rocks and metallic iron was only used for the practical purposes of direction finding, particularly navigation with a compass. Motors, generators, and electrical distribution networks appeared only in the 19th century after the discovery of the deep connection between electricity and magnetism. Magnetic order is a collective phenomenon akin to superconductivity and superfluidity that involves a very large number of particles. The rich variety of magnetically ordered states in solids, not only ferromagnetism but also antiferromagnetism, ferrimagnetism, and a range of noncollinear structures, was confirmed only in the middle of the 20th century, with the availability of neutron beams in research reactors. A range of new magnetic materials are taking their place as active layers in thin film sensors and memory devices (Baltz et al., 2018). Besides information storage (Blundell, 2001), important technical applications include magnetic resonance imaging (MRI) and the use of magnetic nanoparticles in medicine.

Many outstanding discoveries in magnetism and magnetic materials have resulted in rapid advances in information storage technology. Over the last two decades spintronics has emerged as an important field of research both from the point of view of fundamental science and advanced technological applications (Yamaguchi et al., 2021; Pinarbasi and Kent, 2022). The giant magnetoresistance (GMR) effect, the spin Hall effect, and the spin galvanic effects are typical examples of developments in the field. Spintronics aims at understanding how the spin degree of freedom of the electrical carriers can be controlled in order to obtain devices with new functionalities and better performance. This endeavor often combines concepts from different aspects of condensed matter systems, giving the topic a fascinating interdisciplinary flavor. Spintronic phenomena are now being studied in an impressive range of different materials ranging from metals to half-metals to semiconductors, graphene and other two-dimensional systems such as transition metal dichalcogenides.

⁵For a recent review on butterflies in graphene, see for example Chakraborty and Apalkov (2015).

⁶However, as one of the authors of this Encyclopedia has (somewhat humorously) pointed out, this butterfly has Lebesgue measure zero, that is, it cannot fly!.

⁷A wonderful account of the use of magnetism in medicine since ancient times can be found in Mourino (1991).

The GMR effect and the related tunnel magnetoresistance effect (TMR) found their first commercial use in magnetic field sensors for hard-disk read-heads, before broadening their field of application to include magnetic sensors for the automobile industry, solid-state compasses, biosensors, and nonvolatile magnetic memory (Hartmann, 2000). The ability to manipulate the magnetic state of ferromagnetic structures led to initial developments in spintronics, where the spin direction was controlled by externally applied magnetic fields. However, the push for downscaling and faster timescales has prompted research advances in the past decade where the manipulation of magnetic configurations is achieved by local electric currents (the spin torque effect) (Brataas et al., 2012; Locatelli et al., 2014). In recent years, various novel concepts, such as chiral spintronics, skyrmionic spin textures, and magnetic domain walls in spintronics, have been actively pursued. The rate of progress in spintronics is truly astounding (Editorial, 2022).

In the past century, superconductivity has raised many theoretical challenges and triggered numerous technical developments. Discovered in mercury in 1911, this unique phenomenon occurs when the electrical resistance of many metals and alloys drops to zero when cooled below about 4 K, the temperature of liquid helium. More significantly, the material expels magnetic flux and becomes perfectly diamagnetic. Superconductivity has been adopted or evaluated for a wide range of technical applications (Rogalla and Kes, 2012). These include electric power generation, electric power transmission, high-speed maglev transportation, and ultra-strong magnetic field generation in high-resolution MRI and other nuclear magnetic resonance (NMR) systems. Interestingly, it took almost 50 years after the original discovery for the phenomena to be explained by the BCS theory (Tinkham, 2004) of reciprocal-space electron pairing, via the electron–phonon interaction. This electron–phonon mediated superconductivity became known as “conventional superconductivity” after the discovery of “high-temperature superconductivity” (Müller and Bednorz, 1987) at liquid nitrogen temperatures in tetragonal copper oxides in 1986. This threw open a new challenge to explain the properties of strongly correlated *anisotropic* electronic systems. Further new classes of superconductors that remain to be properly understood include the iron-based pnictides discovered in 2008 (Hosono et al., 2018). Recently, a two-dimensional superlattice made from a twisted bilayer of “magic angle” graphene was found to exhibit unconventional superconductivity (Cao et al., 2018), driven by electron–electron interactions.

The phenomenon of spontaneous symmetry breaking (SSB) is ubiquitous in physics, and plays a fundamental role in CMP, particle physics, and even in cosmology. A classic illustration of SSB being Heisenberg’s 1928 paper on ferromagnetism (Heisenberg, 1928). It is responsible for various collective modes, such as the famous Nambu-Goldstone (NG) and Higgs modes. Named by Baker and Glashow (Baker and Glashow, 1962), SSB corresponds to the case where the ground or lowest-energy state does not have the symmetry of the underlying dynamics. Instead, multiple degenerate ground states are available and the symmetry breaking is *spontaneous* because it is not clear, a priori, which one of those ground states will be chosen. In this well-trodden territory a simple analogy of this abstruse concept given by A. Salam is illuminating (CERN, 1977): “Imagine a banquet where guests sit at round tables. A bird’s eye view of the scene presents total symmetry, with serviettes alternating with people around each table. A person could equally well take a serviette from his right or from his left. The symmetry is spontaneously broken when one guest decides to pick up from his left and everyone else follows suit.” Over the years, development of the concept of SSB has taken a circuitous route (Gaudenzi, 2022): “from the land of particle physics to the physics of many bodies (solids and nuclei), from there to the province of superconductivity, and from the latter back to particle physics” SSB’s significance extends beyond the physics of the Higgs boson to the study of low-energy phenomena such as superconductivity, superfluidity, magnetism, and others. Historically, the particle physics community has been guided by this exploration in their quest to understand and discover particles like the Higgs boson. More to the point, when a continuous symmetry is spontaneously broken, a gapless mode, the NG mode, appears which governs the low-energy behavior of the system. As an example, in a solid, the acoustic phonon is the NG mode associated with translational symmetry breaking and determines the behavior of the specific heat at low temperature (the Debye T^3 law). Recently, signatures of Higgs and Goldstone modes have been proposed to exist in a perovskite oxide (Marthinsen et al., 2018), in other crystalline structures (Vallone, 2019), and also in various other quantum systems (Léonard et al., 2017). On a lighter note, it is the symmetry breaking that is claimed to have prevented the fabled donkey (Weintraub, 2012) in the parable by Jean Buridan (1300–50) from dying of starvation (Fubini, 1974).

Common to the theoretical descriptions of these phenomena across CMP and high-energy physics is Quantum field theory (QFT). QFT was originally developed to describe the fundamental processes in high-energy physics, but has now become a valuable tool to address problems across physics, in particular, in CMP (Fradkin, 2013; see also, Mustafa, 2023), statistical physics, modern quantum chemistry, and even in

pure mathematics (Folland, 2008). Advances in our understanding of strongly correlated electron systems in CMP such as high-temperature superconductivity and the FQHE have been aided by the QFT. It has facilitated the treatment of spontaneous symmetry broken states, such as superfluids. Interestingly, many of the conceptual developments in CMP have, in return, had a reciprocal impact in QFT. A spectacular example being Nambu's work in dynamical symmetry breaking (Weinberg, 1986; Nambu, 2009) in particle physics, based on the BCS theory of superconductivity.

A glass is a noncrystalline solid obtained by quenching a liquid. It has a liquid-like structure, but a transition from liquid to solid behavior occurs on cooling. It may have one of a continuum of possible ground states that exhibit frozen-in liquid-like disorder. The term “spin glass” was coined by B.R. Coles (Mydosh, 1993) in 1970 for a diluted magnetic material with frozen-in paramagnetic-like spin disorder where the magnetic moments interact with randomly varying positive or negative exchange interactions leading to a multitude of possible ground states with different, random orientations of the spins. As in a normal glass, the energy barriers between the continuum of metastable states prevent it from ever reaching equilibrium. This phase of condensed matter has been an important and productive area of research. Spin-glass models are conceptually simple, but embody sophisticated physics. These models have become a paradigm for the solution of complex optimization problems (Mézard, 2022): much like the undulating flight patterns of starlings around the skies over Rome (Parisi, 2023). After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and it slowly evolves. This aging phenomenon corresponds to the growth of a “spin-glass order” parameter, whose correlation length can be measured (Joh et al., 1999). A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved (Refregier et al., 1987; Bouchaud et al., 2001). Many glassy materials present aging, and rejuvenation and memory effects can be found in other cases, but they are usually less pronounced. Numerical simulations of these phenomena are under active investigation using custom-built computers (Baity-Jesi et al., 2023; Vincent, 2023). A general understanding of glassy systems, to which spin glasses bring some special insight, is being pursued. It was realized decades ago that the physics of spin glasses has deep connections with the behavior of complex biological systems. In fact, spin-glass type states in neural network models offer interesting insights into states of high and low brain activity, as observed in mammals (Recio and Torres, 2016). These analogies are potentially useful for applications in fields such as robotics and artificial intelligence (AI) (Andriuschenko et al., 2022).

One of the most spectacular phenomena in CMP, discovered in the last century, was Bose-Einstein condensation (BEC). This macroscopic quantum phenomenon had its genesis in the work of Satyendra Nath Bose (Bose, 1924; Blanpied, 1972; Tomczyk, 2022) (whose name is forever associated with bosons), and has fascinated physicists for decades, ever since the first observation of this exotic state of matter in an ultracold gas of rubidium atoms (Georgescu, 2020). Among the advances made in this field, we highlight only a few: simulation of correlated electron states, such as the FQHE state and a bosonic analog of the Laughlin state, and the famous BEC-BCS crossover from a BEC to a BCS superfluid of weakly bound Cooper pairs, as the interparticle interaction strength is varied. Noteworthy is the recent measurement of the dynamic structure factor in an ultracold Fermi gas of lithium-6 atoms in the “unitary” limit, where a linear phonon mode for low momentum transfer can be clearly discerned (Biss et al., 2022). Perhaps such a method might one day shed light on the Laughlin quasiparticle gap and the collective modes that are still largely unresolved (Chakraborty and Pietiläinen, 1988, 1995; Halperin, 1983; Clark and Maksym, 1989).

Liquid helium, ^4He , and the less common isotope ^3He are unique quantum systems (Volovik, 2009). They remain liquid even at absolute zero temperature, a direct manifestation of Heisenberg's uncertainty principle and zero-point energy. The light mass of helium atoms and their weak interatomic attraction leads to a substantial zero-point kinetic energy and the system remains in the liquid state at ambient pressure. Solidification occurs when a pressure of about 25 MPa is applied. The different quantum statistics of the two helium isotopes (^4He is a boson while ^3He is a fermion) are responsible for the different physical characteristics of the two systems. Microscopic approaches to understand the ground state and low-energy excitations of the liquid state have occupied researchers for many decades (see for example, Ristig and Clark, 1976; Lam et al., 1977). These highly correlated quantum fluids have been established as systems where the efficacies of different many-body theories can be tested (Kallio and Smith, 1977; Lantto et al., 1977). These systems have been described as Ariadne's thread in this Encyclopedia, where the strongly interacting constituent particles are treated by a variety of ingenious theoretical and experimental approaches. Interestingly, liquid helium has been proposed to be a medium to design multiexcitation detectors to probe *dark matter* (Schutz and Zurek, 2016) in the keV mass limit. Although this looks far afield from CMP, the interface between CMP and high-energy particle physics could inspire new horizons in CMP, as discussed earlier.

CMP also has an enormous impact on our daily lives with unceasing technological innovation stemming directly from the advances in CMP research. It is also closely associated with the progress of our understanding of materials science and mechanical, chemical, and electrical engineering that deals with properties of novel materials and devices. As some authors have very aptly pointed out (Chaikin and Lubensky, 1995): The use and understanding of matter in its condensed (liquid or solid) state have gone hand in hand with the advances of civilization and technology since the first use of primitive tools. So important has the control of condensed matter been to man that prehistoric ages—the Stone Age, the Bronze Age, the Iron Age—are named after the material dominating the technology of the time. In fact, modern civilization is entirely dependent on our deep understanding and practical use of materials, old and new: Steel, glass, and concrete have shaped our modern living with comfort, health, longevity, and material wealth. All around us, from a tiny paper clip to giant skyscrapers, from jet planes to modern medicines, and the ubiquitous plastics that are integrated into nearly all aspects of human life, are testaments to our control over the myriad behavior of materials (Miodownik, 2014). Today, a large number of materials are designed by using principles of quantum mechanics (Freeman, 2002).

The Silicon chip that launched the information age is a great example of the effect of CMP on our daily lives. The scaling of transistors down to the nanometer range has enabled them to be embedded in greater numbers in the all-pervasive electronic devices that have transformed every facet of life all around the world. The transition from room-size to pocket-size computers with ever increasing computational power and memory, that occurred in only a few decades, epitomizes the unrelenting progress made in this direction. Advances in nanoscale research have opened the door to exploration of the natural world at the ultra-small scale (Chakraborty, 2022), with the potential to shape our future world.

Quantum dots (QDs), the quasi-zero-dimensional electron systems, are one of the most extensively studied nanostructures in the past three decades. They represent the ultimate reduction in dimensionality of a semiconductor device. Here the electrons are confined (either electrostatically or structurally) in all three directions and occupy spectrally sharp energy levels similar to those found in atoms (Chakraborty, 1999), hence the popular moniker *artificial atoms* (Maksym and Chakraborty, 1990). QDs and other similar nanostructures (Chakraborty, 2003) offer a rich variety of fundamental phenomena that result from manipulation of single electrons (single electronics) or single spins at the nanoscale. The study of interacting electrons in a QD requires large-scale numerical computations involving matrices of dimensions in the millions (“monster matrices”) (Chakraborty and Pietiläinen, 2005; Pietiläinen and Chakraborty, 2006). QDs are also thought to have vast potential for future technological applications. One prominent example being quantum cryptography where the QDs are used in single photon emitters (Nowak et al., 2014), and in single photon detectors (Shields et al., 2000). Quantum cryptography, in turn, forms the basis of the *quantum Internet* (Liao et al., 2018). Other applications include lasers, and spintronics in quantum computing, entertainment industry (Bourzac, 2013), and even in biology (Bruchez and Holz, 2007).

Research in recent years has increasingly revealed that quantum phenomena are also ubiquitous in the natural world (Ball, 2011). They govern how birds are able to navigate around the globe using Earth’s magnetic field or how plants use photosynthesis to harvest sunlight for conversion to chemical energy. All depend on subtle quantum effects that are now coming to light, thereby ushering the topic of quantum biology into CMP. Deoxyribonucleic acid (DNA), the molecule responsible for storage of genetic information in the cells of all living organism, is entrusted with the task of preserving, copying, and transmitting information that are necessary for living beings to grow and function. It is often referred to as the body’s hereditary material as DNA is replicated and transmitted from parents to their offspring. This “molecule of life” was discovered in 1869 by Friedrich Miescher in Tübingen, Germany, who called it “nuclein,” as it was isolated from the nucleus of white blood cells (Dahm, 2005; Thess et al., 2021). It took more than eighty years from that momentous event, to discover that DNA has a right-handed double-helix structure with appropriate base pairing (Watson and Crick, 1953; Klug, 2004). That discovery was so important that it has been compared with the discovery of the atomic nucleus in physics (Frank-Kamenetskii, 1997). Understanding the structure of the atom heralded quantum physics, while understanding of the structure of DNA brought forth the field of molecular biology.

DNA has several remarkable properties that make this molecule a prime candidate for nano-electronic materials (Chakraborty, 2007). These include molecular recognition and the ability to self-assemble via the complementarity of the base sequences on the two strands, which means that DNA can be integrated error-free in current semiconductor technology. DNA can also detect information about its own integrity that can trigger its eventual repair mechanism. All these properties are perfectly suitable for developing nanoscale electronics involving DNA

(Taniguchi and Kawai, 2006). Despite the promise of harnessing biology to realize integrated molecular electronics remains fascinating, much work remains to be done to make it a reality (Braun and Keren, 2004).

Protein molecules play a vital role in all living organisms. They are described as Nature's robots (Tanford and Reynolds, 2001) because for every imaginable task required in a living organism, and for every step of that task, there is a protein designed to carry it out. These proteins are even programmed to know when to turn on or off. Just as the twenty-six letters in the alphabet can spell out hundreds of thousands of words, there are twenty different naturally occurring amino acids that can be combined into many more different proteins than there are atoms in the known universe! Protein's biological function is determined by its unique and native three-dimensional structures that are characteristic of individual proteins (Gomes and Faísca, 2019; Echenique, 2007). The question of how proteins fold to their unique, compact, and highly organized functional states has remained an enduring challenge ("The protein-folding problem") (Chan and Dill, 1993; Dill and MacCallum, 2012; Wolynes and Eaton, 1999). Recently, there has been a tremendous development in this area of research. In November 2020, an AI program called AlphaFold, designed to tackle the problem of protein folding, predicted the three-dimensional structures of almost every protein known to science—about 200 millions in all (Jumper et al., 2021). AlphaFold uses a machine learning methodology to bring together information from preexisting knowledge of protein structures, and other geometric and physical constraints to predict protein structures. While this has been heralded a watershed moment in structural biology (Perrakis and Sixma, 2021), there are many key questions that AlphaFold cannot address yet. These include aspects of protein behavior that cannot be understood from a static structure, such as how proteins respond to their environment or how intrinsically disordered proteins actually are organized. Some authors (Nasser et al., 2021) have likened it to solving a crime story: while AlphaFold presents a snapshot in time, the question about how we get there remains unanswered. Biological systems have developed elaborate mechanisms to ensure that proteins fold correctly, or otherwise, they are detected and degraded before any serious harm can result to the host organism. However, protein misfolding does happen and that misfolding in the cell is linked to an array of diseases, including cancers, cardiovascular disease, type II diabetes, and numerous neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. NMR spectroscopy has been an important technique to study protein folding where valuable insights are gained into many aspects of the folding process (Jane Dyson and Wright, 1996).

In this Encyclopedia, we strive to present a taste of all the developments in CMP described above (and much more), written by experts in the field. We are keenly aware that many important and interesting topics are not covered here. However, that is not for want of trying. As some authors had rightly pointed out (Hoddeson, 1992): The field is huge and varied and lacks the unifying features beloved of historians, neither a single hypothesis or set of basic equations underpin the field, as in quantum mechanics or relativity theory, nor a single spectacular and fundamental discovery such as uranium fission for nuclear technology or the structure of DNA for molecular biology. CMP owes what unity it has simply to a common concern with solid and liquid materials. This encompasses such a large range of theories and methods that the field resembles a confederation of interest groups rather than a single entity. Clearly, the task of collecting everything in one place is a monumental endeavor, but we do hope that our compilation of a large number of chapters in this five-volume work, covering a broad range of in-depth descriptions of varied phenomena in CMP will be a treasured source of facts and ideas for the community.

It is undeniably true that there would have been no Encyclopedia without the extraordinary contributions of the large number of authors whose valuable time and efforts brought this project to fruition. My sincere thanks to all of them. I also wish to extend my deep appreciation to the staff at Elsevier for their skillful handling of this huge project. The cover image was created by Hong-Yi Chen from National Taiwan Normal University. The image below was created by Elisabetta Collini, one of the authors. My deepest appreciation to them for taking the time to do this work. Finally, my sincere thanks to the Section editors, Vladimir Fomin, Ana Sanchez, Roberto Raimondi, Hideo Aoki, Rudolf Römer, and Robert Blick for the effort they all expended, that has contributed to the success of this venture. Special thanks go to Vladimir Fomin and Ana Sanchez for securing a large share of the chapters and for their enduring help in providing valuable advice and support to bring the project to fruition. Thanks are also due to many of my friends and colleagues, in particular, Michael Coey, Jürg Fröhlich, Sinéad Griffin, Peter Maksym, Eric Vincent, and Jakob Yngvason for their careful and critical reading of the introduction.

Abstract

This chapter describes Low energy electron microscopy (LEEM) and several other imaging, diffraction and spectroscopy methods, which can be combined with LEEM in the same instrument, and illustrates their application in condensed matter physics by a number of examples. After a discussion of the fundamental electron-solid interactions on which these methods are based an overview over the instrumentation needed for them is presented. The application examples include studies of clean surface, chemical reactions on surfaces, oxidation, growth and structure of thin films without and with gas/substrate reaction, electronic structure determination on the sub-micron scale and applications in thin film magnetism.

Key points

- Imaging with low energy electrons
- Study of surface and thin film phenomena
- Thin film magnetism

Introduction

Modern surface science, thin film science, and in particular, nanoscience needs characterization methods with high lateral resolution. The most prominent of these methods are scanning probe methods such as scanning tunneling microscopy and atomic force microscopy that probe the topmost layer of a surface with atomic resolution. Scanning imaging is slow. For the study of dynamic processes real time imaging is needed, frequently also a somewhat larger and somewhat tunable probing depth. This is provided by elastic reflection of slow electrons that has been used for many years in low-energy electron diffraction (LEED) in the structure analysis of the top several layers of crystals. Similar to the diffracted fast electrons in conventional transmission electron microscopy (TEM), diffracted low-energy electrons can also be used for imaging in low-energy electron microscopy (LEEM) though not with the high lateral resolution that scanning probe microscopy and transmission electron microscopy provide. Essential features of LEEM are not so much the tunable sampling depth but the well-defined wavelength, the high sensitivity to surface topography, and the spin-dependent interaction of slow electrons with magnetic materials that allows imaging of the magnetization distribution on surfaces and in thin films in spin-polarized LEEM (SPLEEM).

Understanding the image formation in LEEM and SPLEEM requires an understanding of the electron–specimen interaction and of the electron optics needed to form an image with the reflected electrons. This chapter describes briefly electron–specimen interaction, image formation, instrumentation and illustrates the application of LEEM and SPLEEM with a number of examples. Examples are also given for imaging with photoelectrons, both in real and in reciprocal space, which is frequently used together with

[☆]*Change History:* August 2022. E Bauer updated all sections. All figures are either modified (Figs. 1–4, 6, 8, 16) or new (Figs. 5, 7, 9–15, 17). Old figures (6, 9, 11–15) have been eliminated.

Fig. 1 (a) Specular reflectivity of two W surfaces for slow electrons. (b) Electron reflection coefficient from a tungsten (110) surface, (1) without, (2) with surface barrier. (1991) *Solid State Communications* 38: 973–976. With permission from Pergamon Press Ltd.

LEEM in the same instrument. More detailed information can be found in a book (Bauer, 2014), book chapters (Bauer, 2019; Tromp, 2019) and review papers cited in them.

Electron–specimen interaction

Electrons are scattered in matter elastically and inelastically. Elastic scattering in the backward direction determines the number of electrons available for imaging. Contrary to the fast electrons used in TEM, which are nearly completely scattered in the forward direction, low-energy electrons are also strongly scattered in the backward direction. This is illustrated in Fig. 1a for 180° scattering at normal incidence from two surfaces of a W single crystal. In single crystals, the backscattered electrons are focused by diffraction into narrow beams whose intensity is determined by diffraction, that is, by the periodicity of the crystal, and by the scattering potential of its constituents. The different periodicity normal to the two surfaces shown in Fig. 1a causes the strong difference in reflected intensity and is one of the major contrast mechanisms in LEEM, called diffraction contrast. Different periodicity causes different electronic band structure, which is reflected in the energy dependence of the intensity (Fig. 1b), taking damping by inelastic scattering and the surface barrier into account. Other diffracted beams selected by an aperture may also be used for imaging. They give information on the lateral periodicity of the surface. When the specimen is not a single crystal with a low index surface but more complex (e.g., vicinal surface or polycrystalline) imaging is always possible with aperture-selected beams, though experimentally more tedious. Because there are no diffracted beams in amorphous specimens, LEEM is possible only upon defocus and in very special cases such as via magnetic contrast. For all these reasons, LEEM and SPLEEM are mainly used for the study of specimens with strong preferred crystal orientation, which allows image acquisition at video rates and therefore the study of the dynamics of surface processes.

The wave nature of the electron, which is a basic requirement for diffraction, can also be used in other ways to produce image contrast. Optical path differences of the electrons reflected from the terraces adjoining a surface step produce phase contrast that can be made visible by lens aberrations and/or defocusing. This so-called step contrast is illustrated in Fig. 2a to make the monoatomic steps on a Mo(110) surface clearly visible. Another contrast mechanism that rests on the wave nature of the electron is the so-called quantum size contrast. In a thin film with parallel boundaries and thickness t , standing electron waves can form whenever $n\lambda/2 + \phi = t$, where λ is the wavelength and ϕ represents the phase shift at the boundaries. This causes reflectivity differences between regions with different thicknesses as illustrated in Fig. 2b, similar to the interference phenomena in thin films in light optics. The energy ($E \sim \lambda^{-2}$) dependence of the reflectivity (Fig. 2c) can also be described in a simple band structure model as shown for Cu films on W(110) (Altman et al., 1998). At very low energies local field variations caused by surface potential differences or surface roughness produce work function contrast and topographic contrast, respectively. These contrast mechanisms are most pronounced when the electrons are reflected immediately in front of the surface, that is, when the instrument is operated in the mirror mode (mirror electron microscopy (MEM)). MEM does not require crystalline surfaces and, thus, is widely applicable.

In SPLEEM magnetic contrast is obtained making use of the different reflectivity for electrons with spin polarization $\mathbf{P}$ parallel or antiparallel to the magnetization $\mathbf{M}$ in the near surface region as illustrated in Fig. 3a and b. In the difference images (Fig. 3a and b) the structural features of the surface are eliminated, resulting in a contrast, which is proportional to the magnetization. Similarly, with $\mathbf{P}$ perpendicular to $\mathbf{M}$ the difference image (Fig. 3d) shows the magnetization in the domain wall between the domains seen in Fig. 3c.

Fig. 2 (a) Monatomic steps on a Mo(110) surface. Sublimation and glide steps are visible, electron energy 14 eV. (b) Quantum size contrast in a Fe layer on a W(110) surface. The film thickness varies from terrace to terrace as indicated in the top image taken with 11.0 eV electrons. A comparison with the bottom image, taken with 16.4 eV electrons, illustrates the dependence of the contrast upon thickness and energy. (c) Spin-dependent energy dependence of the reflectivity of 5, 6 and 7 monolayer thick Fe films on W(110). (a): Reproduced from Teliens W., Bauer E. Fig. 3 Imaging of the magnetization distribution in a thin Co layer on a W(110) surface with SPLEEM. Images (a) and (b) are taken with opposite direction of the polarization $\mathbf{P}$ parallel to $\pm \mathbf{M}$. Their difference image (c) eliminates the structural features and the detector defect and shows only the magnetic domains while the difference image taken with $\mathbf{P} \perp \pm \mathbf{M}$ (d) shows the domain walls (electron energy 2 eV). Reproduced from Bauer E., et al. (1996) LEEM studies of the microstructure and magnetic domain structure of ultrathin films. *Journal of Magnetism and Magnetic Materials* 156: 1–6, with permission from Elsevier.

Before turning to the influence of inelastic scattering on LEEM, one important difference between the scattering of fast and slow electrons has to be mentioned. While the scattering of fast electrons by atoms can be described to a good approximation by the first Born approximation, which predicts increasing scattering strength with increasing nuclear charge Z , this is not true any longer for the backscattering of slow electrons. The backscattering cross section does not vary monotonically with increasing Z or energy E . Atoms with small Z may backscatter in certain energy ranges much more than atoms with large Z . For example, at about 50 eV Al and Si backscatter much stronger than W. Therefore, there is no analog in LEEM to the Z contrast in transmission electron microscopy (TEM).

Inelastic scattering of the electrons determines the sampling depth of LEEM unless elastic backscattering is very strong and inelastic scattering weak. Inelastic scattering involving small energy losses, such as excitation of lattice vibrations or spin waves in magnetic specimens, is not eliminated from the image by the energy-dispersive elements of present LEEM/SPLEEM instruments and thus does not limit the sampling depth. The sampling depth is limited by energy losses of say more than 0.5–1 eV, to give a rough limit. These electrons do not contribute to the image formation. In electron spectroscopy, the sampling depth is normally defined by the inelastic mean free path λ_i that takes into account all losses ranging from single electron excitation to collective electron (plasmon) excitation to inner shell ionization. Its energy dependence is usually described by a universal curve, which is a good approximation for many materials at energies above about 50 eV but breaks down in the energy range mainly used in LEEM (≤ 20 eV). Here, the energy loss mechanisms are strongly material-dependent. For example, in noble metals such as Au, λ_i may be as large as several nanometers whereas in graphene (Geelen et al., 2019) and in 3d metals such as Fe (Zdyb and Bauer, 2013), it is only a few tenths of a nanometer. Surface and depth sensitivities are thus strongly material-dependent.

Fig. 4 Schematic of a LEEM instrument. (a) Basic instrument setup, (b) illumination system of a SPLEEM instrument, (c) imaging system for a spectroscopic instrument (“SPELEEM”) and (d) aberration-corrected LEEM (“ACLEEM”). For explanation see text. The locations of the first image and diffraction planes are indicated in (a) by an arrow and dotted line, respectively.

Instrumentation

Because of the high surface sensitivity of low-energy electrons, the instruments using them require ultrahigh vacuum (UHV) and surface cleaning facilities. For electron-optical reasons, the electrons are decelerated from high energy as they approach the specimen. This is done in a so-called cathode lens whose light-optical analog is the immersion lens. In order to be able to observe the image of the surface, the illumination beam has to be separated from the imaging beam by a beam separator. This leads to a system configuration as schematically shown in Fig. 4a. Lens 1 produces a demagnified image of the electron source (cathode C)—or more precisely of the “crossover” in front of C—which is imaged by lens 2 into the back focal plane of the objective lens O. In the objective lens—which also includes the specimen S—the electrons are decelerated from the high initial energy, typically 10–20 keV, to the desired low energy, which is determined by the potential difference between cathode C and specimen S. After reflection from the surface, the electrons are accelerated again to high energy. The objective lens produces the diffraction pattern of the specimen in its back focal plane and a first intermediate image in the middle of the beam separator B. The subsequent lenses produce further intermediate images and lens 4 allows switching between imaging the specimen and its diffraction pattern, which is imaged by lens 5 into the image plane I. The brightness of the image is enhanced by a pair of channel plate multipliers so that it is high enough on the final fluorescent screen to be recorded with a CCD camera with short image acquisition times. The electron lenses are, in general, magnetic lenses but electrostatic lenses are used too. The magnetic beam separator B is designed so as to minimize the unidirectional focusing by its magnetic field. Not shown in Fig. 4a are the deflection elements needed for beam alignment, the stigmators for correction of the astigmatism of the electron-optical components, and the apertures needed for confining the angular acceptance of the system and for selecting the specimen area contributing to the LEED pattern. The first aperture, the so-called contrast aperture, is placed in the intermediate image of the diffraction pattern produced by lens 3, the second one either in the first intermediate image of the specimen in the beam separator or into the symmetric position in the illumination beam. Various beam separators are used with deflection angles ranging from 16° to 90°.

The heart of the microscope is the objective (cathode) lens because it determines the resolution and transmission of the microscope. Cathode lenses have much larger chromatic and spherical aberrations than the lenses used in TEM. Therefore, the acceptance angle α has to be strongly limited by the “contrast aperture” in the diffraction pattern. While in TEM the contrast aperture may accept many diffracted beams, which allows one to reach resolutions in the 0.1 nm range, in LEEM only one diffracted beam, usually the (00)-beam, and its immediate environment can be used for optimum resolution. The best resolution achieved without aberration correction is about 4 nm, using a field emission cathode that has a narrow energy distribution and, thus, minimizes the chromatic aberration, which is dominant at low energies. Most instruments use magnetic cathode lenses because of their somewhat lower aberrations and higher transmission. Resolution can be increased somewhat by monochromatizing the illumination beam but significant resolution improvement requires aberration correction, which is possible with an electron mirror M. Insertion of this mirror requires transfer of the first image into a second beam separator and decelerating/accelerating optics (Fig. 4d). Calculations for mirror correctors predict resolutions of about 1 nm and somewhat less (Tromp et al., 2010; Schramm et al., 2012). In the laboratory about 1.5 nm has been achieved while commercial instruments such as the one shown in Fig. 5b claim resolutions of

Fig. 5 Commercial LEEM instruments. (a) A SPELEEM with horizontal electron optics, 60° beam separator and energy filter (upper left), top view (ELMITEC, courtesy Mentec T. O.). (b) An ACLEEM with vertical electron optics, 90° beam separator and aberration corrector (hidden below support system), side view (courtesy SPECS Surface Nano Analysis GmbH). The instruments have attachments for sample transfer and preparation, evaporators, gas and light sources allowing in-situ studies of surface processes at pressures from 10^{-10} to 10^{-5} mbar.

better than 2 nm. The routine resolutions of 10 nm in uncorrected instruments (Fig. 5a) are largely determined by the stability of the specimen and by local charging, not by the electron optics.

Extensions of the basic LEEM instrument shown schematically in Fig. 4a are the SPELEEM instrument and the LEEM instrument equipped with an imaging energy filter (Fig. 4c), called spectroscopic photo-emission and low-energy electron microscope (SPELEEM) because it allows also spectroscopic photoemission microscopy and spectroscopy. SPELEEM requires a different illumination system schematically shown in Fig. 4b. The electron source is now not a field emitter or a LaB_6 cathode as used in LEEM but a GaAs(100) single crystal surface which has been exposed to Cs and an electronegative gas, usually O_2 , so that the lowest point of the conduction band of GaAs is slightly above the vacuum level. This surface is illuminated with circular polarized light from a laser with an energy $h\nu$ corresponding to the direct bandgap of GaAs so that electrons excited from the top of the valence band into the bottom of the conduction band can be emitted. Due to optical selection rules, up to 50% of the photoemitted electrons are spin-polarized with their spin perpendicular to the surface. With strained multilayer superlattice photocathodes a spin-polarization of 100% is theoretically possible, in practice 90% has been achieved. Changing the helicity of the light from right to left circular polarization inverts the spin direction, characterized by the polarization vector $\mathbf{P}$. When a magnetic surface with local magnetization $\mathbf{M}$ is illuminated with these electrons, then the reflected intensity not only depends upon the topography and crystal structure, but also upon $\mathbf{P} \cdot \mathbf{M}$. The difference image between two images taken with opposite directions of $\mathbf{P}$ eliminates all nonmagnetic contrast and shows only the distribution of $\mathbf{M}$. In order to determine the direction of $\mathbf{M}$ completely, $\mathbf{P}$ must not only be inverted but adjustable in any direction. This is achieved with the 90° electrostatic/magnetic deflector D and a spin rotator lens R. Pure electrostatic deflection leaves $\mathbf{P}$ unchanged; in pure magnetic deflection, $\mathbf{P}$ rotates along with the direction of the beam, and mixed deflection allows one to cover all $\mathbf{P}$ directions between these two directions, that is within the plane of the drawing of Fig. 4b. The rotator lens allows $\mathbf{P}$ rotation around the beam direction, which is out of this plane so that all directions are accessible. Alternately, $\mathbf{P}$ rotation in any desired direction can be achieved with a Wien filter (Yasue et al., 2014). Usually the direction normal to the specimen surface and two preferred directions in it are selected. Fig. 3 illustrates the application of these possibilities.

In the SPELEEM, the imaging column is modified by inserting an energy filter and adding additional lenses at its output. In the example shown in Fig. 4c, the energy filter is a 180° electrostatic analyzer in which the electrons are retarded to a fraction of the input energy and reaccelerated at its output to the input energy again. Energy selection is made by a slit in the dispersive plane at the exit of the energy filter. By choosing the excitation of the pre-filter lenses 4 and 5 and of a lens in the filter, either the energy-filtered image or the diffraction pattern can be obtained with the lenses behind the filter. These can also be used to image the dispersive plane and thus to do electron spectroscopy from small specimen regions selected by the field-limiting aperture. An energy resolution of about 0.2 eV can be obtained without much loss of intensity in LEEM and LEED. The advantage of energy filtering in LEEM and LEED is the elimination of secondary electrons, which can cause a strong background in specimens with large electronic band gaps. The main application of the energy filter is however in X-ray photon-excited secondary electron emission microscopy, usually called XPEEM, in which the filter allows selection of a small energy window in the wide secondary electron energy distribution and thus improves the resolution. A second application is in XPEEM with photoelectrons from inner shells characteristic for the specimen composition. Fig. 5a shows the presently most widespread SPELEEM.

Applications

Clean surfaces

Because of its importance in microelectronics, Si is the material that has been studied most extensively. The discovery in 1985 that the “reconstruction” of the Si(111) surface with bulk periodicity into one with sevenfold periodicity at about 1100 K, the Si(111)- $(1 \times 1) \rightarrow \text{Si}(111)\text{-(}7 \times 7\text{)}$ transition, is a first-order phase transition, demonstrated the power of LEEM. It also clearly showed the limitations of laterally averaging studies because surfaces with the same LEED pattern produced completely different LEEM images as shown in Fig. 6. The transition between the two surface terminations and the diffusion processes involved have been subject of many LEEM studies.

The most important Si surface in semiconductor industry is the (100) surface. It has $p(1 \times 2)$ and $p(2 \times 1)$ reconstruction alternating between terraces separated by monolayer steps whose direction-dependent roughness changes simultaneously as illustrated in Fig. 7a. Extensive work on Si(111) and Si(100) surfaces has not only brought a detailed understanding of these surfaces but has contributed immensely to the understanding of processes on clean surfaces such as surface diffusion, adatom density, two-dimensional nucleation, step dynamics, and stability. Images of the Si(100) surface (Fig. 7), taken with illumination tilted in one of the $p(2 \times 1)$ directions to produce contrast, illustrate some of these processes: (b) isotropic monolayer by monolayer sublimation starting from hole nuclei, (c) anisotropic growth during Si deposition caused by step anisotropy and

Fig. 6 Coexistence of (7×7) regions (bright) and (1×1) regions (dark) on a quenched Si(111) surface. The surface in (a) was annealed for a long time at 1150 K, that in (b) was quenched directly from 1450 K (electron energy 11 eV). (c) LEED pattern of the two surfaces. (d) unidirectional growth during B segregation from heavily B doped Si caused by disappearing S_A step energy (for details see Hannon et al., 1998). Segregation of bulk impurities to clean metal surfaces can cause much stronger surface changes. Examples are S and C in transition metals.

Chemisorption, chemical reactions and oxidation

The fast image acquisition time of LEEM images combined with diffraction over a wide temperature range makes LEEM very powerful for the study of surface processes such as chemisorption and surface reactions up to pressures in the middle 10⁻⁵ mbar range. As an example Fig. 8 shows the use of LEEM and LEED in the study of the catalytic reaction NO + H₂ → N₂ + H₂O on the Rh(110) surface under conditions in which the reaction oscillates. In this experiment, the LEEM chamber is used as a continuous flow reactor in the 10⁻⁷–10⁻⁶ mbar range. Starting at defects chemical waves propagate across the surface causing different surface compositions along the propagation direction with characteristic LEED patterns corresponding to pure N, mixed N + O and pure O coverage. Fig. 8a shows the time dependence of the intensity of the characteristic LEED spots, converted into a distance scale via the known pulse velocity. Selecting a small surface region with an aperture and imaging with these diffracted beams allows following the chemical composition of the wave in real space (Fig. 8b).

Oxidation at low temperatures usually leads to a poorly ordered or amorphous layer for which LEEM is not well suited. Annealing causes crystallization and breakup of the layer into many small oxide crystals whose number decreases while their size increases with increasing temperature, a process for which dark field imaging with characteristic LEED spots is well suited. An example is the NiAl(110) surface oxidized at 325 °C. Images were taken with diffracted beams of the substrate and of the two oxide domains, which form on this surface after annealing up to the decomposition temperature of 1015 °C (McCarty, 2001). LEEM imaging is not only possible at room temperature after annealing but also during oxidation at high temperature. Fig. 9 illustrates this with real time images of the oxidation of the NiAl (110) surface at 955 °C in about 1 × 10⁻⁷ mbar O₂. The antiphase boundaries are quite mobile at the high temperature and are attributed to relaxation of the strain between the alumina island and the substrate. The first crystal nucleates at a step, a second one with many antiphase boundaries grows along a step.

Another example of the example of LEEM combined with selected area LEED is the oxidation of the Ru(0001) surface at elevated temperature at which RuO₂ crystals with complex shapes and several epitaxial orientations grow with increasing temperature (Flege and Grinter, 2018 and references therein).

Thin film growth

The study of the growth of thin films and their structural/chemical changes with temperature and environment is one of the main applications of LEEM. Thin films can be grown by a variety of methods. An example is graphene, the most studied thin film. It can be grown by decomposition of hydrocarbons which is possible on many surfaces or by decomposition of the near surface regions of SiC. In the former method large areas with constant thickness can be produced, in the latter this is in general not the case as shown in Fig. 10a. The pronounced energy-dependent intensity variations in the image indicate strong reflectivity differences whose cause can be determined by selected area I(V) measurements (Fig. 10b): the quantum size oscillations in the direct energy gap below about 5 eV show that these differences are due to thickness differences.

Monolayer and bilayer graphene films have been studied extensively because of their unusual electronic structure (linear band dispersion, Dirac cone) and their possible application in microelectronics. The contact with the substrate has a mayor influence on the properties of these layers and can be reduced significantly by inserting atoms or molecules between the layer and the substrate (intercalation). This is illustrated in the images and I(V) curves in Fig. 11. Exposure of a graphene monolayer on Pt to CO causes a dramatic decrease of reflectivity at 1.5 eV and in the I(V) curve due to the decoupling of graphene from the substrate by CO intercalation. The ability to intercalate molecules has let to studies of catalysis under cover (Fu and Bao, 2017).

Thin films are grown in general in situ by deposition of the film material on single crystal surfaces provided that the material does not dissociate during evaporation/sublimation. The growth mode and structure of the film depends on substrate temperature, orientation, surface treatment, deposition rate, angle of incidence of the vapor beam and background pressure and is frequently monitored with video image acquisition. The video frames in Fig. 12 of the growth of Pb films at similar rates in the 10^{-10} mbar range on various Si surfaces illustrate some of these dependences. In (a) and (c) Pb was deposited on the clean surface, first forming a Pb wetting layer. On top of it isolated three-dimensional Pb crystals with (111) orientation nucleate and grow, initially (e.g., in (c)) by supply from extremely mobile Pb atoms adsorbed on the wetting layer, later (e.g., in (a)) predominantly directly from the incident vapor. The dominant lateral supply of atoms at large island distance (c) and the slower diffusion on top of the islands causes rim formation and concave islands. On the vicinal Si surface (d) Pb crystals nucleate at the Au-decorated steps and the fast supply of the atoms from the wetting layer on the terrace causes fast growth along the steps and normal to the surface. Three-dimensional growth can be suppressed by depositing first a layer that strongly interacts with Si and Pb (“interfacient”), which causes quasi-layer-by-layer growth as illustrated in (b). This type of film growth occurs also in film-substrate systems with very small misfit at least up to several monolayers and has been studied extensively with LEEM.

While monatomic films can be grown from one source most compound films require reactive growth on the substrate, either from volatile compound sources as for example used in compound semiconductor growth or in the presence of reactive gases. In situ growth of III–V and II–VI compounds is generally avoided because of system contamination but the growth of oxide films at pressures up to the 10^{-5} mbar range poses no problems. The growth of rare earth oxide films, some of which are important in catalysis, is an example and illustrated for the case of praseodymium oxide in Fig. 13. Crystals nucleate at steps and step bunches and grow

Fig. 13 Growth of praseodymium oxide films on Ru(0001) by deposition of Pr in about 7×10^{-7} mbar O_2 at 760 °C. (2017) Growth and structure of ultrathin praseodymium oxide layers on ruthenium(0001). *Physical Chemistry Chemical Physics* 19: 3480–3485. (g) and (h): Adapted from Flege J.I., et al. (2017) Nanoscale analysis of the oxidation state and surface termination of praseodymium oxide ultrathin films on ruthenium(0001). *Ultramicroscopy* 183: 61–66. With permission from Royal Society of Chemistry and Elsevier, respectively.

lateral and vertical in triangular islands, which form with increasing coverage bands along the steps, separated by oxygen-covered substrate regions. At large thickness their topography becomes very complex. The comparison of LEEM image pixel-by-pixel $I(V)$ measurements with calculated $I(V)$ curves and data from similar oxides reveal a considerable structural heterogeneity across the bands attributed to oxygen content variations.

In the case of rare earth oxide growth on Ru or Ir surfaces substrate material is not part of the layer. In the growth of other compound films the substrate supplies one of the film components, the other coming from the gas phase or from impurities in the substrate. Examples are the growth of Si nitride films by nitriding the Si surface with active nitrogen or ammonia and carbide films by segregation from carbon-doped metals.

Sometimes reactive film growth is unintentional, a case being the growth of Fe nanowire films on ZnS(100) with the goal of spin injection into ZnS. In the first study about 1 nm thick Fe films were deposited at 200 °C and annealed at 400 °C. This produced two types of nanowires, previously identified as Fe by transmission electron microscopy, diffraction and energy-dispersive spectroscopy. An in situ SPELEEM study of the growth of these wires, using all the characterization modes available in this instrument at a synchrotron light source (Fig. 14), however, showed that one type of the wires had reacted with the substrate. This was achieved by combining LEEM with selected area LEED, X-ray photoemission microscopy (XPEEM), selected area XPS and X-ray magnetic circular dichroism PEEM (XMCDPEEM). While the LEED pattern of crystal A can be attributed to the substrate and to Fe covered with an adsorbate, that of crystal B could not be identified. The local XPS spectra show that the adsorbate on A is S and that crystal B is not Fe but a Fe-S compound. This allowed interpretation of the weak spots in the LEED pattern of crystal B as one of several $Fe_{1-x}S_x$ compounds, two of which are magnetic. XMCDPEEM (not shown here) limited their number to these two sulfides, which have different Curie temperatures. Measurement of the temperature dependence of the magnetic contrast finally lead to the identification of crystal B as Fe_3S_4 (greigite). This example shows that LEEM and LEED sometimes need to be combined with spectroscopic and magnetic imaging for complete sample characterization.

Band structure analysis

The band structure of the unoccupied states of solids is generally determined by inverse photoelectron spectroscopy. As already discussed at the beginning, the energy dependence of the LEEM intensity depends strongly on the band structure $E(k)$. Therefore measurement of the intensity of elastically reflected beam allows to measure $E(k)$. This was done first using the quantum well oscillations at normal incidence on epitaxial (110)-oriented Fe films with well-defined thickness shown in Fig. 2c. The extrema of the quantum well conditions define the $k_{\perp}$ values for a given energy E . Analysis of the data obtained with spin-polarized electrons gave the data points shown in Fig. 15a. This method has been used successfully also for other materials such as MgO, epitaxially grown on a Fe(100) surface (Wu et al., 2006) but gives only $E(k)$ for k normal to the surface. It is limited to thin films exhibiting constant thickness regions large enough for selection them in LEEM with an aperture.

Band structure information for non-normal $\mathbf{k}$ can be obtained by measurements of the intensity of specular reflected electrons as a function of $k_{\parallel}$ and E in selected $k_{\parallel}$ directions (angle-resolved reflected-electron spectroscopy (ARRES)). This is shown in Fig. 15b for graphene grown on SiC(0001). The data are from three monolayer thick regions (marked C in Fig. 10a), whose $I(V)$ curves have three quantum size minima (Fig. 10b) corresponding to quantum well states. At energies between about 6 and 15 eV the reflectivity is high due to the large band gap of graphene in this energy range. The images are taken for discrete E , $k_{\parallel}$ values, evident in the square pixels, for two $k_{\parallel}$ directions, Γ M and Γ K. The correlation between these plots, which are representative for the density of unoccupied states, and the band structure is better visible in Fig. 15c, in which the data are taken in smaller E , $k_{\parallel}$ steps and with a higher dynamic range and compared with the calculated band structure. Detailed explanation of the measured data requires calculations taking the energy-dependent damping by inelastic scattering and boundary effects into account as it was done in the comparison between experiment and theory in Fig. 1 for $\mathbf{k}$ normal to the surface.

The band structure of occupied states is usually determined with angle-resolved photo-electron spectroscopy (ARPES) without spatial resolution. SEPLEEM allows band structure studies with 1 μm resolution as already shown in early work (Schmidt et al., 1998). This is important in the study of heterogeneous systems. Such a system is graphene (GR) on Ni(111) grown by chemical vapor deposition at high temperatures. Upon cooling to room temperature Ni carbide forms via carbon segregation from Ni as illustrated in Fig. 16. The LEEM images (a, c, d), taken with the beams marked in the LEED pattern (b), indicate two large area graphene phases I (EG), II (RG) and a high density of small (≤ 250 nm) irregular shaped patches III in phase II. Selected XPEEM images, taken at energies around the C 1 s level in the manner as in Fig. 14, show that the patches III (RGC) are carbide. Measurements of $E(k)$ with photoelectrons around the K points show Dirac cones for all three phases with different positions and shapes, indicating different interaction with the Ni substrate. The dark field XPEEM images taken with K point electrons show that the Dirac point of phase III is close to the Fermi level, indicating decoupling from Ni. Together with the local XPS spectrum the decoupling is attributed to local Ni carbide formation. Phases I and II are strongly coupled to Ni though somewhat different as seen in position and shape of the Dirac cone.

Spin-polarized LEEM

SPLEEM has found many applications in thin film physics largely motivated by the importance of ultrathin films in spintronics. SPLEEM has led to the understanding of the magnetic domain structure and domain wall structure in films ranging from monolayer to thick films. Of pure scientific interest has been the co-called spin reorientation transition with increasing thickness or temperature, mostly between in-plane and out-of-plane. For more practical importance is the interlayer exchange coupling between ferromagnetic layers through a nonmagnetic layer. This depends upon interlayer material and thickness and the spins are either parallel or antiparallel in the ferromagnetic layers. Fig. 17 shows a more complex case, a Co/Au/Co sandwich. The bottom Co layer has strong in-plane magnetization with large domains and small out-of-plane magnetized regions. Three Co monolayers on top of the Au layer enhance the out-of-plane component of the magnetization while simultaneously strongly reduces its in-plane component. Adding four more monolayers Co produces pure but complex in-plane magnetization consisting of a parallel and a 90° rotated component. This so-called biquadratic exchange coupling is caused usually by roughness but occurs also in perfect layer systems. In tri-layer systems the coupling is dominated by quantum size effects because of the different wavelength of spin-up and spin-down electrons. For example in the Co/Au/Co system the [1–10] component of the top layer is antiferromagnetic coupled when the Au interlayer is only five monolayers thick instead of the ferromagnetic coupling seen in Fig. 17. SPLEEM is ideally suited for this kind of studies.

Fig. 16 Graphene on Ni(111). Left: LEED pattern and LEEM images taken with the (00) and diffracted beam shown in (b). Right: Photoelectron $E(k)$ spectra taken with photoelectrons in a plane through the K point normal to the Γ -K direction, indicated in the photoelectron diffraction patterns (insets). Far right: Darkfield XPEEM images taken with electrons at the Dirac points as marked by arrows. Adapted from Africh et al. (2016) Switchable graphene-substrate coupling through formation/dissolution of an intercalated Ni-carbide layer. *Scientific Reports* 6: 19734-1-8. With permission from Nature Portfolio.

Fig. 17 SPLEEM images of the interlayer coupling between Co layers through a 6 monolayer (ML) thick Au film grown on a W(110) surface. The spin direction of the incident beam is along the two high symmetry in-plane directions and along the surface normal ([110]). Top: 7 ML Co, center: 3 ML Co on 6 ML Au on 7 ML Co, bottom: 7 ML Co on 6 ML Au on 7 ML Co. The images of the Au-covered Co layer are nearly identical to those in the top row. With permission of the American Physical Society.

An emerging field in SPLEEM studies is skyrmion physics, which is not only of fundamental interest but also motivated by the drive for higher and higher bit density in magnetic storage devices. Skyrmions may be considered as magnetic nanobubbles and may be suitable for bubble memories provided that they are stable at room temperature without an external applied field and can be fabricated in reproducible manner. The first goal can be achieved with suitable thin film structures as shown in Fig. 18. A double layer consisting of 2.5 ML Fe and 2 ML Ni is out-of-plane magnetized with $\mathbf{M}$ pointing in opposite directions forming stripe domains with constant chirality domain walls. Application of a sufficiently high magnetic field $\mathbf{B}$ normal to the surface eliminates the domains with opposite $\mathbf{M}$. Within a narrow $\mathbf{B}$ range the stripes break up into skyrmions (Fig. 18b and c). The field necessary for skyrmion formation is provided by the magnetic field of a thick Ni layer with perpendicular magnetization through a Cu layer (interlayer exchange coupling, Fig. 18a). All layers are grown in situ in the SPLEEM instrument and are epitaxial. Small skyrmions with a narrow size and shape distribution as shown in Fig. 18 form only in a limited Cu thickness range (8.5 ML). With increasing thickness (decreasing $\mathbf{B}$) the size and size/shape distribution increases significantly (Lo Conte et al., 2020). The color wheel presentation of the SPLEEM image in Fig. 18d and e shows the direction of the spins in a skyrmion, Fig. 18f the three-dimensional spin structure. Finer details require better resolution, which is expected from aberration corrected SPLEEM instruments (Yu et al., 2020).

Conclusion

LEEM is only one of many methods for the study of materials possible in a LEEM instrument. Only some of them have been discussed here. LEED and I(V) analysis are standard, so is mirror electron microscopy (MEM), thermionic emission microscopy and UV radiation-excited photo emission electron microscopy. Standard methods in LEEM instruments with an energy analyzer at synchrotron radiation sources are various modes of XPEEM, X-ray magnetic imaging, selected area XPS and ARPES. Laterally resolved ARPES has developed into a separate field, momentum microscopy (Tusche et al., 2015, 2020). It does not require a beam separator but can be done simpler in a PEEM instrument with an energy filter and for magnetic imaging with a spin selector.

Abstract

The current chapter provides the reader with a general introduction of Mössbauer effect following by its unique utilization, which became known as Mössbauer spectroscopy. Mössbauer spectroscopy is based on the recoilless emission and following resonant absorption of gamma radiation by atomic nuclei and has been at the scientific forefront of physics, chemistry, biology, mineralogy for more than 60 years. Soon after the discovery of the Mössbauer effect, it became obvious that this effect can be used to study various properties of materials on a microscopic scale via hyperfine interactions with an unprecedented resolution. This was the beginning of a new analytical tool - Mössbauer spectroscopy. Today, it has developed into a standard analytical technique used in many laboratories and big research facilities. The current chapter provides the reader with a general introduction, explains the underlying hyperfine interactions and gives examples of the possible application of the method.

Nomenclature, Symbols, Units

a, a_A	Isotopic abundance
a_A	Atomic density ($1/\text{cm}^3$)
B	Magnetic field (T)
c, c_0	Speed of light (m/s)
d_A	Absorber thickness (m)
E	Electric field (V/m)
e	Elementary charge (A s)
E_0	Transition Energy (eV)
E_m, E_g, E_e	Energy levels of states, excited, ground state (eV)
f	Area fraction
fD, fA	Debye-Waller factor
g, g_N	Landé factor

[☆]*Change History:* November 2022. P Schaaf and D Zybkin updated this chapter. Tables are intact. A new section about Emission Moessbauer Spectroscopy was added, this section includes 1 new figure. List of references has undergone an update, from the recommended literature, to literature based on which the authors wrote the chapter. In the second revision of it several figures were updated to fit the updated style of the encyclopedia, namely figures: 1,2,4,5,6,10,12,13.

$h, \hbar$	Planck constant (J s, eV s)
I	Spin, nuclear spin
$I, I_0, I(\nu), I(E)$	Intensity (counts)
m	Magnetic quantum number
M	Mass, atomic mass
p	Momentum ($\vec{p} = \hbar \vec{k}$)
R, R_e, R_g	Nuclear radius (m)
t_A	Effective thickness ($t_A = \sigma_0 f_A N_A d_A a_A$)
V	Electric potential (V)
v	Velocity (m/s)
V_{zz}	Field gradient (V/m ²)
Z	Atomic number
α	Conversion coefficient
Γ	Line width (FWHM) (eV, mm/s)
γ	Photon, radiation
δ	Isomer shift, shift (eV, mm/s)
η	Asymmetry parameter
θ	Angle
λ	Wavelength ($v \cdot \lambda = c$)
ν, ω	Frequency ($\omega = 2\pi\nu$)
σ, σ_0	Cross section, maximum cross section (barn)
τ_n	Life time (s)
Ψ	Wavefunction

Introduction

The discovery of the recoilless nuclear resonance emission and absorption in solids has recently celebrated its 60th anniversary. Although the resonance absorption of gamma rays by nuclei is analogous to the well-known optical phenomenon of resonance fluorescence and the underlying physics of the phonon theory of the lattice (Debye) and its quantum mechanical theory (Dirac, Lamb) had been well known before and nuclear resonance absorption had already been predicted in 1929, it was only in 1957 that Rudolf L. Mössbauer discovered this phenomenon during his doctoral studies (Mössbauer, 1958a, b). So it took a long time to combine nuclear physics with solid state physics and to transfer absorption and emission resonances from the electron shell to the nucleus. This recoilless nuclear resonance absorption was named after R. L. Mössbauer, who was awarded the Nobel Prize in 1961, and has been known as the *Mössbauer Effect* since then. This effect is an easy way to eliminate the recoil energy loss that occurs during the emission and absorption of photons. Consequently, γ -lines of the highest possible sharpness could be obtained and applied. Soon after the discovery of the Mössbauer effect, it became obvious that this effect can be used to study various properties of materials on a microscopic scale via hyperfine interactions with an unprecedented resolution. This was the beginning of a new analytical tool - Mössbauer spectroscopy. Today, it has developed into a standard analytical technique in many laboratories (Frauenfelder, 1962).

It is the purpose of this article to first give a short introduction to the basic physical processes and the hyperfine interactions, to sketch the typical experimental setup, and then to show how this can be applied as a unique analytical tool to many problems in solid state physics. For more details and further reading, we refer to the bibliography, where the physical principles and applications of the Mössbauer effect and Mössbauer spectroscopy are described in great detail in a series of textbooks (Wertheim, 1964; Murad and Cashion, 2004; Greenwood and Gibb, 1971; May, 2012). Regarding the most recent developments of the method, the current original literature has to be searched, for a recent review is still missing. Nonetheless, there are several interesting directions taken for the future applications, such as significantly improved signal processing, and combining the focusing polycapillary with Mössbauer spectroscopy. The latter allows one to perform unique investigation of tiny samples in the anvil cell, especially if such approach is combined with on-line studies (Abrecht et al., 2015; Novak et al., 2019; Kočiřčák et al., 2022; Zyabkin et al., 2020). Furthermore, the ongoing new developments with respect to the synchrotron-based methods (e.g. Nuclear Resonance Scattering) deserve a separate article.

The nucleus and nuclear radiation

When either an atom or a nucleus undergoes a transition from an excited state (E_e) to a lower or the ground state (E_g), a quantum of electromagnetic radiation (a photon) is emitted. This photon, in turn, can induce the opposite transition in an atom or nucleus of the same kind. This principle of resonant emission and absorption is sketched in Fig. 1.

If a nucleus in an excited state with a mean lifetime of τ_N (e.g. $\tau_N = 141$ ns for ^{57}Fe) emits γ -radiation, the energy distribution $I(E)$ follows the Breit-Wigner law (Lorentzian):

$$I(E) = I_0 \cdot \frac{(\Gamma/2)^2}{(E - E_0)^2 + (\Gamma/2)^2} \quad (1)$$

Fig. 1 Schematic view of resonant emission and absorption. States with a finite lifetime are spread in energy according to the Heisenberg uncertainty principle, as indicated for the excited levels. This gives rise to a Lorentzian shape in the energy distribution of the corresponding emission (absorption) line.

Fig. 2 Principles of emission and absorption with and without recoil. In the upper part a free atom involves a free atom involves recoil for emission and absorption. If the atom and thus the nucleus is bound in a lattice, the recoil is transferred to the whole lattice if the springs are tight enough. The shaded area represents the probability for resonance absorption.

where E_0 is the transition energy ($E_0 = E_e - E_g$) and $\Gamma \equiv \hbar/\tau_N$ is the resonance width (FWHM) ($E_0 = 14.401$ keV, $\Gamma = 4.7 \times 10^{-9}$ eV for ^{57}Fe). The momentum of the γ quantum is $\vec{p} = \hbar\vec{k}$.

Momentum conservation for the emission process causes the energy available for the emission process to be shared by the emitted quantum and the recoiling atom or nucleus. A free atom of mass M emitting a γ -quantum will experience a recoil with the energy $E_r = p_\gamma^2/2M$, which is generally much larger than the natural line width Γ ($E_r = 2 \times 10^{-3}$ eV is much higher than $\Gamma = 4.7 \times 10^{-9}$ eV for ^{57}Fe).

As the same is true for the absorption process also the absorption energy is increased by the recoil energy of the absorbing nucleus. Thus, the energy shifts by the recoiling nuclei are big enough to preclude resonance absorption of the emitted photon by other nuclei. This is sketched in Fig. 2 for the free atom. The shifts lead to an only very small overlap of the emission and absorption Lorentzians and thus a very low probability of resonance, illustrated in Fig. 2 by the shaded area.

If the nucleus is bound in a solid and the springs in Fig. 2 are strong enough, i.e. the atoms are bound rigidly, the recoil goes to the whole lattice, and the recoiled mass M is drastically increased ($M \rightarrow 10^{16} M$). Thus, the recoil energy E_r becomes negligibly small. Since the lattice does not consist of rigid springs, in other words the phonon system (the spring) is a quantized system, there is a certain probability that lattice vibrations (phonons) will be excited and the recoil of the atom is transferred to phonons. On the other hand, there is also a high probability that no phonons will be excited and the whole solid takes the recoil. Thus, in a solid for a certain fraction of nuclei, the emission and in an equivalent manner the absorption, occurs without recoil energy loss. The chance that the emission takes place without inducing any phonons is called, in analogy to X-ray diffraction, the Debye-Waller factor,

$f_D = \exp(-k^2 \langle x^2 \rangle)$, when $\vec{k}$ is the wave vector of the photon and $\langle x^2 \rangle$ the mean square displacement of the nuclei (atom). This factor – sometimes more accurately called Lamb-Mössbauer factor – depends on the temperature T , the energy of the γ -quantum $k = E_0/(\hbar c)$, and the Debye temperature Θ_D (representing the stiffness of the lattice springs) of the solid:

$$f_D(T) = \exp \left(-\frac{3\hbar^2 k^2}{4Mk_B \Theta_D} \left[1 + 4 \left(\frac{T}{\Theta_D} \right)^2 \int_0^{\Theta_D/T} \frac{y}{\exp(y) - 1} dy \right] \right). \quad (2)$$

The fraction of recoilless emission or absorption is $f_D = 0.76$ for ^{57}Fe in $\alpha\text{-Fe}$ with $\Theta_D = 470$ K at room temperature and thus allows fast measurement of the nuclear resonance, the Mössbauer effect. For the sake of completeness, it should be mentioned that the Debye Waller factors can be different in different crystallographic directions, causing the Goldanski-Karyagin effect, which leads to an anisotropy in the observed line intensities (Melzer, 1981).

Another decisive factor for the feasibility and speed of the measurements is the cross-section of the absorption. It determines the probability of a photon with matching energy to be absorbed by the corresponding nucleus. This cross-section σ is given, together with the maximum cross-section σ_0 , as a Lorentzian by

$$\sigma = \sigma_0 \cdot \frac{\left(\frac{\Gamma}{2}\right)^2}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2} \quad (3)$$

The maximum cross-section can be determined from the nuclear spin number I in the excited and ground state, the photon wavelength λ , and the internal conversion coefficient α via

$$\sigma_0 = \frac{\lambda^2}{2\pi} \cdot \frac{2I_e + 1}{2I_g + 1} \frac{1}{1 + \alpha}. \quad (4)$$

The internal conversion coefficient α represents the ratio of the number of γ quanta interacting upon emission with the electron shell and thus leads to the emission of conversion electrons and conversion X-rays to the number of γ quanta with undisturbed emission, i.e. the resulting probability of the γ emission is $\frac{1}{1 + \alpha}$.

In order to obtain the γ quanta, one has to populate the excited state; in other words, we need a source for the Mössbauer radiation. This is normally achieved easily via parent isotopes, which then decay to the corresponding nucleus in the excited state. Such a source is illustrated in Fig. 3, where the decay scheme of the ^{57}Co source for ^{57}Fe Mössbauer spectroscopy is shown. The ^{57}Co isotope decays via electron capture to the excited state of ^{57}Fe . The half-life of ^{57}Co is about 272 days, so that with such a source one can easily measure for a couple of years. The parent isotopes are normally produced by nuclear reactions (neutron, deuterons, protons) in reactors or in accelerators and are commercially available. In addition, the radioactive isotopes are embedded into an appropriate matrix - normally chosen to be a cubic nonmagnetic material - in order to achieve a high Debye-Waller factor and a single line source. Embedding in magnetic material can give multi-line and polarized sources for certain applications. ^{57}Co is mostly embedded into the fcc Rh metal as the source for Fe Mössbauer spectroscopy.

From the effect to spectroscopy

In the case of recoil-less emission and absorption, one observes extremely sharp γ lines, the so-called *Mössbauer lines*. The width of these lines is often much smaller than the line shifts caused by interactions between the emitting or absorbing nuclei and their environment in the solid. For this reason, the Mössbauer effect is very suitable for resolving and measuring hyperfine interactions via a Doppler modulation of the γ energy by moving the source and the absorber relative to each other with velocity v .

$$E(v) = E_0 \cdot \left(1 + \frac{v}{c} \right) \quad (5)$$

Fig. 3 Schematic view of the ^{57}Co source for ^{57}Fe Mössbauer spectroscopy. The energy levels, spins, probabilities, and lifetimes are indicated.

Fig. 4 Schematic view of the setup for measuring a Mössbauer spectrum in transmission geometry. The source is moved in a controlled way and the photons are detected in a detector (HV-high voltage), whose signals are amplified (Amp). The single channel analyzer (SCA) selects only those signals corresponding to the desired Mössbauer transition. These counts are stored in the computer for the respective drive velocities.

Usually, the source is moved and the velocities required for ^{57}Fe lie in the range of 10 mm/s, which can easily be produced and controlled in the lab.

Another Doppler effect is caused by the thermal vibrations in the lattice. The atoms and nuclei in source and absorber have a finite temperature, have thermal energy and are thus vibrating. As we have seen before, the movement causes a shift in energy, but the thermal velocities are isotropic and thus the positive and negative velocities cancel each other, leading to only a small broadening of the spectral lines. Nevertheless, there are also relativistic effects, which are causing a net shift of the energies with the temperatures, which is called *second order Doppler shift* (SOD).

$$\delta_{\text{SOD}} = \frac{\bar{v}^2}{2c^2} E_0 \quad (6)$$

The standard geometry of Mössbauer spectroscopy is the transmission geometry (TMS - transmission Mössbauer spectroscopy), which is shown schematically in Fig. 4.

The sample is irradiated from the source and the absorption is measured with a detector behind the sample. The source is moved by a drive system (constant acceleration, sinusoidal or constant velocity) and the emitted and Doppler-modulated photons are heading through an aperture toward a detector. Only those quanta are counted that have the involved transition energy E_0 . Gas filled proportional counters or solid state detectors are most widely used for that purpose. For the measurement, the sample is placed in between source and detector and absorbs photons at certain energies represented by a certain source velocity. Of course, this absorption is again followed by emission, but it is directed to the detector any more, but emitted more or less homogeneously into the full 4π solid angle (and additionally diminished by the internal conversion process). This way, one obtains a velocity-correlated intensity spectrum $I(v)$, which then contains all the information from the Mössbauer effect. These Mössbauer spectra are stored in a multichannel scaler. Sometimes, source or absorber (sample) are put into a cryostat, an oven, or a magnetic field, etc. in order to measure temperature-dependent effects or the effects of certain physical situations. If the sample is too thick, then there is no count rate left behind it and multiple absorption and emission processes can influence the spectra. If the sample is too thin, there are not enough nuclei for the absorption process, and not enough statistics for analysis is available (there is always non-resonant background). To be concise, one has to solve the full Hamiltonian (transmission integral) to find the absorption spectrum ($I(E) \sim I(v)$). Nevertheless, one can derive an analytical solution for the transmission integral (i.e. the folding of the emission, absorption and re-emission over the sample), if the absorber can be treated as a thin absorber. The effective thickness of the absorber (sample) t_A is given by

$$t_A = \sigma_0 f_A N_A d_A a_A, \quad (7)$$

with the maximum cross section σ_0 , the recoilless fraction (Debye-Waller-factor) f_A , the atomic density N_A , the absorber thickness d_A , and the abundance of the Mössbauer isotope a_A . For ^{57}Fe at room temperature we have the following values: $\sigma_0 = 256.6 \cdot 10^{-20} \text{ cm}^2$, $f_A \approx 0.75$, $N_A = 8.476 \cdot 10^{22} \text{ atoms/cm}^3$, $a_A = 2.19\%$. The effective thickness should have values of $t_A \approx 1$, allowing fast measurements with the thin absorber approximation still valid. Then we have the simple folding of the emission and the absorption spectra (with their respective energy eigenvalues E_i or ν_i), resulting in a Lorentzian line again.

$$I(v) = I_0 - I_{\text{abs}} \frac{\Gamma^2}{(E - E_0)^2 + \Gamma^2} \quad (8)$$

In this thin absorber approximation this results in the double line width (more general by the sum of source and absorber line width: $\Gamma = (\Gamma_S + \Gamma_A)$).

If the absorber becomes thicker, the lines become somewhat broader due to multiple re-emission and absorption effects and for thick samples one has to solve the full transmission integral.

A calibration of the Mössbauer spectrometer is carried out by measuring standard materials with well known properties. For Fe, calibration is usually performed using a 10–25 μm α -Fe foil at room temperature (α -Fe: $B_{hf} = 33 \text{ T}$ or 10.6245 mm/s). All isomer shifts are normally related to the center of the α -Fe spectrum at room temperature. The spectra are fitted according to a least squares routine by superimposing Lorentzian lines in simple cases or by more sophisticated theories for complicated samples.

If a sample consists of several sites or phases, the relative area of the corresponding set of Lorentzians gives the atomic fraction of the Mössbauer spy isotope in the site or phase. To calculate the real fraction, this area has to be corrected by the Debye-Waller factor. The latter is hardly known, so it has to be determined experimentally. As a simplification, it is often assumed that all subspectra and all phases have the same Debye-Waller factors f_D and neglecting (most of the times) smaller errors caused by that. Thus, the phase fraction can be identified with the relative fractions (areas) of the phases in the Mössbauer spectrum (Conser, 1981).

The isotopes most frequently used for Mössbauer spectroscopy are (listed according to their importance): ^{57}Fe , ^{119}Sn , ^{151}Eu , ^{121}Sb , ^{125}Te , ^{197}Au , ^{129}I , ^{155}Gd , ^{161}Dy , and some others. Their properties are summarized in Table 1.

Internal conversion

The effect of internal conversion plays an important role in Mössbauer spectroscopy. It is most important for lower mass numbers and becomes negligible for very heavy atoms. For a certain fraction of nuclei, the emitted photon does not leave the atom, but spends its energy for kicking off an electron from the shell - a conversion electron. As a result of internal conversion, conversion electrons, and subsequently a cascade of Auger electrons and conversion X-rays are emitted. They too can be used for the measurements, since they contain the same information as the originally absorbed (emitted) photon. This internal conversion is shown in Fig. 5.

If the electrons originating from the internal conversion process are detected for the Mössbauer measurement, this is called CEMS $\equiv$ Conversion Electron Mössbauer Spectroscopy. Because the electrons cannot penetrate detector windows the samples have

Table 1 Properties of the most frequently used Mössbauer isotopes.

Isotope	a [%]	E_0 [keV]	τ_N [ns]	I_e	I_g	σ_0 [10^{-20} cm^2]	2Γ [mm/s]	E_r [10^{-3} eV]

a - natural isotopic abundance, E_0 - transition energy, τ_N - half lifetime, I_e and I_g - nuclear spin quantum number of excited and ground state, σ_0 - maximum resonance cross section, Γ - natural line width (FWHM), E_r - recoil energy of a free atom.

Fig. 5 The internal conversion process during emission of γ -radiation. Instead of the photons also conversion electrons can be emitted leading to a cascade of Auger electrons and conversion x-rays.

Fig. 6 Mössbauer measurements in backscattering geometry leading to CEMS and CXMS. In combination with TMS this is resulting in STRMS.

to be mounted inside an appropriate detection system. Depending on the material and the electron energies, the electrons can only escape from the sample surface within 10–500 nm. Therefore, CEMS is especially suited for the investigation of surfaces and thin films (up to a depth of some 100 nm for Fe-Mössbauer spectroscopy) and even able to measure the properties of a monolayer (Schatz et al., 1996).

Also the conversion X-rays or re-emitted γ radiation can be used to measure the Mössbauer effect in the samples under investigation. This method is named CXMS $\equiv$ Conversion X-ray Mössbauer Spectroscopy. The X-rays can penetrate about 10–30 μm of most metals and thus the information depth of CXMS is in this order. For such backscattering measurements as visualized in Fig. 6 in reasonable times, special detectors with large solid angles have been developed.

Based on the different information depths of the different modifications of Mössbauer spectroscopy, it is especially interesting to measure these different radiations simultaneously. Simultaneous measurements achieve a discrete depth profile of the measured samples. The arrangement for the simultaneous measurement of all three modifications was named STRMS $\equiv$ Simultaneous Triple Radiation Mössbauer Spectroscopy. It should be noted again that the sampling range in the case of iron-based materials for the CEMS measurements is about 150 nm, while for CXMS it is 10–20 μm and TMS scans the whole sample (Gonser, 1975).

Hyperfine interactions

Hyperfine interactions are based on effects caused by the interplay between the atomic nucleus and its electronic environment. As early as in 1924, Wolfgang Pauli interpreted the hyperfine structure of atomic spectral lines by the magnetic coupling between the nucleus and its electronic shell and also predicted properties of the Zeeman and Paschen-Back splittings in the presence of a nuclear magnetic moment. So the hyperfine interactions were merely an extension of the fine structure and observed in the atomic spectra with increasing resolution of the experiments in atomic physics.

The high energy resolution of the Mössbauer effect (as well as that of other nuclear methods like nuclear magnetic resonance or perturbed angular correlation) allows the direct observation of the hyperfine interactions, i.e. the change of the energy levels due to electric or magnetic fields acting at the Mössbauer nucleus. These interactions are mainly the electric monopole interaction, the electric quadrupole interaction and the magnetic dipole interaction.

Isomer shift

The electric monopole interaction is the interaction of the nuclear charge Ze with the electron density at the nucleus with finite size. It leads to a difference in the energy states in source (S) and absorber (A), when comparing to a point nucleus (infinite small):

$$E_S = E_0 + \frac{2}{5} \pi Z e^2 |\Psi_S(0)|^2 [R_e^2 - R_g^2] \quad (9)$$

$$E_A = E_0 + \frac{2}{5} \pi Z e^2 |\Psi_A(0)|^2 [R_e^2 - R_g^2] \quad (10)$$

Here, R is the radius of the nucleus in the appropriate state (g - ground state, e - excited state) and Ψ the electron wave function. $e|\Psi(0)|^2$ then gives the electron density at the nucleus. These shifts of the levels (equivalent to the isotope effect in atomic physics) leads to the isomer shift δ as sketched in Fig. 7:

$$\delta = E_A - E_S = \frac{2}{5} \pi Z e^2 [|\Psi_A(0)|^2 - |\Psi_S(0)|^2] [R_e^2 - R_g^2]. \quad (11)$$

Thus the lines for materials with different electron densities at the nucleus are shifted by δ with respect to the undisturbed center. Thus, charge densities in the materials can be calculated from this isomer shift.

Fig. 7 Electric monopole and quadrupole interaction cause a shift and a splitting of the nuclear levels, and accordingly shift and split the lines in the Mössbauer spectrum.

Quadrupole splitting

An electric quadrupole moment of the nucleus eQ , i.e. a non-spherical shape of the nucleus, interacts with an electric field gradient (EFG) acting at the nucleus, which leads to a splitting of the energy levels, as displayed in Fig. 7. Diagonalizing the EFG tensor $V_{ij} = \frac{\partial^2}{\partial r_i \partial r_j} V$ (V = electrical potential) with $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$ and $V_{xx} + V_{yy} + V_{zz} = 0$, the asymmetry parameter η is given by:

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} \quad (12)$$

and the energy eigenvalue for a state with spin I and magnetic quantum number m_I is:

$$E_q(m_I) = \frac{eQV_{zz}}{4I(2I-1)} [3m_I^2 - I(I+1)] \sqrt{1 + \frac{1}{3}\eta^2}. \quad (13)$$

For ^{57}Fe with $I_g = 1/2$ and $I_e = 3/2$, only the excited state splits and the quadrupole splitting ΔE_q is:

$$\Delta E_q = E_q(m_I = 3/2) - E_q(m_I = 1/2) = \frac{1}{2} eQV_{zz} \sqrt{1 + \frac{1}{3}\eta^2} \quad (14)$$

This leads to a doublet in the Mössbauer spectrum, where the splitting, i.e. the distance between the two lines, determines the magnitude of the quadrupole interaction and thus the field gradient. Consequently, charge distributions of atomic arrangements or defect structures can be deduced. Lattices with cubic symmetry and without any defects always result in single lines, because, due to the symmetry, no EFG can be present.

Magnetic splitting

The magnetic moment μ of the nucleus interacts with a magnetic field B acting at the nucleus (Nuclear Zeeman Effect). This interaction gives rise to the splitting of the otherwise degenerated states. The state with spin I splits into $2I + 1$ magnetic substates with the eigenvalues:

$$E_m = -\frac{\mu B m_I}{I} = -g_N \mu_N B m_I, \quad (15)$$

where the magnetic quantum number m_I can have the values $m_I = I, I-1, \dots, -(I-1), -I$. The magnetic moment μ is given by the Bohr magneton μ_N and the Landé factor g_N by:

$$\mu = g_N \mu_N I. \quad (16)$$

Based on the selection rule for absorption (emission) of dipole radiation $\Delta m = 0, \pm 1$, only six transitions are allowed, and they represent the significant Zeeman sextet structure in the Mössbauer spectra of magnetic materials, as demonstrated in Fig. 8.

Mixed hyperfine interaction

If the magnetic dipole interaction and electric quadrupole interaction act together, the eigenvalues cannot be determined as easily as for each interaction alone. Normally, perturbation methods are applied. As the magnetic interaction is usually much stronger, first

Fig. 8 Magnetic dipole interaction causes a splitting of the nuclear levels, and accordingly leads to the typical Zeeman sextet in the Mössbauer spectrum.

the eigenvalues are determined for this magnetic interaction and the electric interaction is treated as a perturbation. For the energy states in a first order perturbation calculation one finds:

$$E_m = -g_N \mu_N B m_I + (-1)^{|m_I|+1/2} \cdot \frac{1}{4} \cdot e Q V_{zz} \cdot \frac{1}{2} (3 \cos^2 \theta - 1 + \eta \sin^2 \theta \cos 2\phi), \quad (17)$$

where θ and ϕ are the angles between the direction of the magnetic field B and the principal axis of the EFG component V_{zz} . For ^{57}Fe we have:

$$E_q = \frac{1}{8} e Q V_{zz} (3 \cos^2 \theta - 1 + \eta \sin^2 \theta \cos 2\phi). \quad (18)$$

Now the line positions for the general case can be given by Eq. (19).

$$\begin{aligned} L_1 &= \delta - g_1 \mu_N B + E_q \\ L_2 &= \delta - g_2 \mu_N B - E_q \\ L_3 &= \delta - g_3 \mu_N B - E_q \\ L_4 &= \delta + g_3 \mu_N B - E_q \\ L_5 &= \delta + g_2 \mu_N B - E_q \\ L_6 &= \delta + g_1 \mu_N B + E_q. \end{aligned} \quad (19)$$

The g-factors g_i result from the Landé-factors of the ground state g_g and the excited state g_e :

$$\begin{aligned} g_1 &= \frac{1}{2} \cdot (3|g_e| + g_g) \\ g_2 &= \frac{1}{2} \cdot (|g_e| + g_g) \\ g_3 &= \frac{1}{2} \cdot (|g_e| - g_g). \end{aligned} \quad (20)$$

The resulting shift of the energy levels and the shift of the inner 4 lines in the spectrum with respect to the our lines 1 and 6 is sketched in Fig. 9.

Fig. 9 Mixed hyperfine interaction: magnetic dipole interaction causes a Zeeman splitting of the nuclear levels and an additional smaller electric quadrupole interaction shifts the split lines, which is also visible in the Mössbauer spectrum.

Fig. 10 Angular characteristics of the dipole radiation: the angle θ is formed by the $\vec{k}$ vector of the γ radiation and the spin direction of the nucleus (i.e. the magnetization direction). The shown emission Mössbauer spectra illustrate some important cases.

Angular dependence of absorption and emission

The relative line intensities I_i for a sextet depend on the angle $\theta = \angle(\vec{k}, \vec{I})$ between the propagation direction $\vec{k}$ of the γ -radiation and the direction of the spin (magnetization) $\vec{I}$, as shown in Fig. 10.

For $\theta = 90^\circ$ the intensity ratio is $I_1 : I_2 : I_3 = 3 : 4 : 1$, whereas for $\theta = 0^\circ$ the lines 2 and 5 disappear and the ratio is $I_1 : I_2 : I_3 = 3 : 0 : 1$. If the directions of magnetization are randomly (isotropic) distributed ($\bar{\theta} = 54.7^\circ$), the ratios are $I_1 : I_2 : I_3 = 3 : 2 : 1$.

This can be used to determine the magnetization orientation in the sample. Mössbauer polarimetry and Magnetic Orientation Mössbauer spectroscopy (MOMS) have evolved as specialized methods for this purpose.

Synchrotron based methods

The improvement of recent synchrotron facilities and the development of new channel-cut monochromators with superior resolution allowed the transformation from the classical Mössbauer spectroscopy in the energy domain into the time domain of nuclear resonance scattering (NRS). Many methods and applications have evolved here, found its application in various structural dynamic studies on a ps - μs timescale. These studies include but not limited to rotation motion and jump diffusion, electronic and magnetic structure of disordered micro- and nano-structures, often under severe pressure and temperature conditions. Unfortunately, here this comprehensive subject cannot be treated and additional information about the method should be obtained elsewhere (Schlage and Röhlberger, 2013; Röhlberger, 2004).

eMS - Emission Mössbauer spectroscopy

In contrast to the traditional transmission arrangement (TMS) described in Section "From the effect to spectroscopy", there exists an alternative approach called Emission Mössbauer Spectroscopy (eMS), where the sample under the scope acts as the source, while we deal with the stable absorber. The emergence of eMS has broadened significantly the scope of physics available to Mössbauer spectroscopy. All the other basic principles remain unchanged, except that now one can choose what to move: either the stable

Fig. 11 Schematic representation of the setup for measuring a Mössbauer spectrum in emission geometry while implanting on-line. The setup consists of the implantation chamber with a mounted sample (source), and a stable-isotope detector installed on a transducer. The signal on the detector is firstly amplified (pre- and amplifier), then single channel analyzer (SCA) facilities in selection of a desired energy range, after this the resulting data is synchronized with transducer's velocity in multichannel analyzer (MCA), which outputs the resulted spectrum. Based on authors previous Elsevier article Zybakin DV, Vetter U., Linderhof FMA, Gunnlaugsson HP, Schaaf P (2020) eMIL: Advanced emission Mössbauer spectrometer for measurements in versatile conditions. *Nuclear Instruments and Methods in Physics Research A* 968: 163973.

absorber or the radioactive sample. Frequently, the desired parent isotope is introduced into the sample by ion implantation, less frequently by electrochemical deposition. In the case of implantation, there are off-line (longlived) and on-line (shortlived) experiments. In the first scenario, activity produced elsewhere is mass-separated and implanted at low energies, while the second approach is carried out at on-line radioactive beam facilities, such as ISOLDE/CERN (Weyer, 2000).

The latter is performed depending on the specific lifetime, where measurements may take place simultaneously with implantation. Implantation of radioactive isotopes induces radiation damage in solids, and the final location of the implanted probes may be of big concern. This is especially the case for heavy ions (≥ 10 keV), when annealing is prohibited and damage cascades of displaced host atoms are formed, thus boosting the local defect density (e.g. interstitials, vacancy clusters). The standard experimental arrangement during emission experiments is depicted schematically in Fig. 11. If the fluence is $> 10^{13} \text{ cm}^{-2}$, and a certain threshold of defects density is exceeded, a formation of local amorphous areas takes place. From a standpoint when no annealing is possible, introduction of probes by electrochemical deposition and following diffusion-annealing could be beneficial, although the surface usually behaves as the sink for the defects and the concentration of the probes (dopant) via this approach is high. In studies at temperatures where the damage is mostly annealed, probe's location is determined by the dynamic equilibrium forces. Controlling the implantation energy, it becomes feasible to perform depth selective studies of the local structure, to follow the rapid local dynamic phenomena on the atomic scale, collective excitation, diffusion, properties of electronic and magnetic structure in both semiconductor and metal physics. There is a growing interest toward possible application in chemistry experiments. Furthermore, employing ion-implantation allows providing a truly dilute concentration ($3 \times 10^{12} \text{ ions/cm}^2$), thus neither perturbing the local environment nor forming precipitates. Besides, various isotopes decay differently and the impact of it varies from the relocation of implanted atoms into interstitial sites to perturbation of the electronic configuration around the probe. The limiting factor for eMS lies in the confined number of radioactive isotopes available and the information, which is not possible to obtain by eMS, hence other hyperfine interaction methods should be looked at.

Applications

One of the first applications of the Mössbauer effect was the proof of the gravitational red shift. Due to its extremely high energy resolution, Mössbauer spectroscopy was able to verify the tiny energy shift of $\delta_{\text{grav.}} = \frac{gd}{c^2} E_0$, which a γ quantum experiences when it falls only $d = 20$ m in earth's gravity g .

Phase analysis

One of the standard applications of Mössbauer spectroscopy is the accurate phase analysis (Stevens and Shenoy, 1982; Mashlan et al., 2003). One of the first examples was the determination of the amount of retained austenite in heat-treated steels. Here, Mössbauer spectroscopy is superior to any other method (e.g. XRD) with respect to its detection limit ($< 1\%$) and accuracy ($< 1\%$). In addition, by using Mössbauer spectroscopy the question of the interstitial arrangements of carbon and nitrogen in the retained austenite could be solved and it also allows an accurate calculation of the carbon or nitrogen content.

Another famous application of Mössbauer spectroscopy is the determination of $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratios in bio-matter, minerals and other oxides for medical, archeological or industrial applications (Long and Stevens, 1986; Long and Grandjean, 1996). Currently, the first Mössbauer spectrometer is doing this even on the surface of Mars.

The excellent resolution of the hyperfine interactions also allows the determination of the magnetic properties of materials, which is especially useful in alloys, magnetic and amorphous materials. Due to the short lifetime of the nuclear states, all dynamic effects occurring in this time regime influence the Mössbauer spectra in shape and line width. This fact has been used to study diffusion and hopping mechanisms, relaxation, superparamagnetism, nanocrystalline materials, effects by rf-fields, and other time dependent effects. More recent developments also deal with Mössbauer diffraction or the production of X-ray lasers.

Site determination

The ability of Mössbauer spectroscopy for determining and quantifying different sites in a phase is demonstrated by a simple example, the iron nitride $\gamma'- Fe_4N .$

This material has an anti-perovskite structure $\text{Pm}3\text{m}$, which is presented in Fig. 12. The iron forms an fcc structure and the nitrogen is located in the center of the unit cubes in an ordered manner. There are two crystallographic iron sites, Fe-I at the corners of the cube and Fe-II at the face centers, both sites having 12 iron nearest neighbors at the same distance. The Fe-I site has no nitrogen nearest neighbor (0 nn N), whereas the Fe-II sites have exactly two nitrogen nearest neighbors (2 nn N).

In contrast to these two crystallographic sites, the Mössbauer spectrum of this material, as shown in Fig. 13, has to be fitted with three subspectra corresponding to three different arrangements for the iron. The hyperfine fields are 34 T for the Fe-I sites and 21.6 T for the Fe-II sites. The difference in the two different Fe-II sites has to be explained by the magnetism of the material, which is invisible for X-ray diffraction.

The hyperfine parameters and the subspectral abundances are summarized in Table 2.

Fig. 12 Crystallographic structure of the cubic γ' - Fe_4N with site assignment explained in the text.

Fig. 13 Mössbauer spectrum at room temperature in transmission geometry of Fe_4N powder. The spectrum is fitted by superimposing 3 Lorentzian sextets, corresponding to 3 different atomic Fe sites in the material as explained in the text.

Table 2 Hyperfine parameters as measured for Fe₄N powder at room temperature.

Site	IS δ [mm/s]	QS E_q [mm/s]	BHF B_{hf} [T]	LW Γ [mm/s]	RA f [%]
Fe-I	0.19(2)	0.00(1)	34.0(2)	0.28(1)	25.0(13)
Fe-IIa	0.27(2)	0.10(1)	21.6(2)	0.28(1)	51.9(09)
Fe-IIb	0.26(2)	-0.22(1)	21.6(2)	0.28(1)	23.1(21)

IS - isomer shift, QS - quadrupole splitting, BHF - hyperfine field, LW - line width, RA - relative area.

The fcc material is ferromagnetic with a Curie temperature of $T_C = 767$ K, i.e. well above the measurement temperature, which in this case is room temperature in this case. The magnetic easy axis is the (100) direction, which is indicated by the z-axis in Fig. 12. There is no electric field gradient for the Fe-I site, but one for the Fe-II site having nitrogen neighbors. Thus, we have to distinguish two cases for the Fe-II site: for site Fe-IIa, the main component V_{zz} is collinear with the hyperfine field B_{hf} , i.e. $\theta = 0^\circ$. For the site Fe-IIb, EFG and z-axis are perpendicular, i.e. $\theta = 90^\circ$. For both cases, the asymmetry parameter is $\eta = 0$ and V_{zz} is identical. From Eq. (17), we see that we achieve E_q with opposite signs and its value is twice as large for the Fe-IIa site as for the Fe-IIb site. This exactly matches the experimental findings in Table 2.

The subspectra areas should behave like Fe-I:Fe-IIa:Fe-IIb = 1:2:1, because 25% of the iron atoms are located at the corners, and Fe-IIa:Fe-IIb = 50%:25% because four Fe-atoms at the face centers have $\theta = 0$ and only two have $\theta = 90^\circ$. This theory is nicely reflected in the experimental results. This example demonstrates the ability and power of Mössbauer spectroscopy in site determination.

Magnetic orientation Mössbauer spectroscopy

For Mössbauer polarimetry, magnetic fields and multi-line Mössbauer sources (e.g. ^{57}Co in Fe gives 6 lines from the source and when measuring Fe with 6 absorption lines, this results in a spectrum of 36 lines) are used to polarize the quanta from the source and thus obtain information about the magnetic domain orientations in magnetic samples. On the other hand, with a proper modification of the traditional Mössbauer technique, with a method called Magnetic Orientation Mössbauer Spectroscopy (MOMS), one is also able to determine the spin distribution in sample. An important advantage of this MOMS technique in comparison to e.g. the Magneto-Optical Kerr Effect technique (MOKE) is the absence of any external magnetic field during the measurements, which may change actual magnetization and spin distribution. Thus, it is also a magnetically non-destructive method.

In standard geometry, the photon beam is incident along the normal direction of the sample. For the MOMS experiments the specimen normal is tilted by various angles α away from the incident γ -beam and then the spectra are measured subsequently after different sample rotations around their normal. This way, the spin distribution can be obtained by fitting the intensity ratio $I_2(\varphi)/I_3(\varphi)$ of the second and the third sextet lines as a function of the various tilt and rotation angles, yielding a 'picture' of the spin distribution in the sample.

Conclusion

In summary, it should have become obvious that Mössbauer spectroscopy is a very powerful method, which has proven its suitability for many problems in solid state and materials physics, chemistry, geology, archeology, environmental and space physics, and even relativistics. Mössbauer spectroscopy is based on nuclear physics, solid state physics and hyperfine interactions. It gives a microscopic image of the Mössbauer spy isotope and its immediate surroundings, which makes the method very powerful to study properties, short range order and dynamic effects in many interesting materials. It is still under development and not used as widely as it should be. This may be due to the fact that 'suppliers' (Mössbauer spectroscopists) and 'customers' (scientists with questions) do not know enough of each other. Especially the new developments of its synchrotron-based branch seem to lead to another push in its applications. Mössbauer spectroscopy should be seen as a powerful analytical tool, which can significantly contribute to answer many open questions for many materials. So ask your questions to a Mössbauer spectroscopist.

Abstract

Spectromicroscopy is a class of experimental techniques that combine spectroscopic performances with high spatial resolution. One important member of this class is photoelectron spectromicroscopy, which is based on the spectroscopic techniques exploiting the photoelectric effect. Two different approaches are discussed here: photon-focusing spectromicroscopy and electron-optics photoelectron spectromicroscopy. The discussion includes a few selected examples, an analysis of relevant performances and a short presentation of the current developments.

Key points

- Photoelectron spectromicroscopy
- Photon-focusing approach
- X-ray lenses: Fresnel zone plates, Schwarzschild objectives, Kirkpatrick-Baez mirrors, compound refractive lenses
- Electron-optics approach
- Photoelectron emission microscope (PEEM)
- Partial yield
- Resolution and sensitivity
- Ultrabright storage ring synchrotron sources
- Free electron lasers

Spectromicroscopy

The term “spectromicroscopy” broadly applies to all spectroscopic techniques implemented with high spatial resolution. The discussion here is focused on a leading example: spectromicroscopy techniques based on the photoelectric effect.

Besides photoemission spectroscopy, other important types of spectromicroscopy are (1) electron energy loss spectroscopy, which can be performed with high spatial and energy resolution providing local information on the electronic and chemical composition and bounding in the material; (2) Auger spectromicroscopy, a surface-specific analytical technique, using a focused electron beam to combine high lateral and depth resolution; (3) X-ray-excited fluorescence spectromicroscopy (“fluorescence microprobe”), a powerful and relatively straightforward technique for microchemical analysis, and (4) near-field vibrational spectromicroscopy, which beats the Abbe diffraction limits of far-field microscopy by exploiting evanescent waves.

The development of photoelectron spectromicroscopy

Photoelectron spectroscopy, a technique based on the photoelectric effect, emerged in the late 1960s as a leading probe of the electronic structure in condensed matter systems. The progress in the experimental tools progressively eliminated its historical limitations of this technique, enhancing its impact and expanding its domains of application. The development of photoelectron spectromicroscopy was a major component of this evolution.

Until the late 1980s, photoemission experiments were performed with almost no lateral resolution—whereas the natural surface sensitivity of the photoelectron emission process automatically provided atomic scale resolution in the direction perpendicular to the emitting surface. Technical problems, primarily related to the low signal level, forced the photoemission experiments to probe a sample area not smaller than $1 \times 1 \text{ cm}^2$ —or even larger. This was a severe limitation in the study of laterally inhomogeneous systems and processes.

In 1988–89, the first examples of photoemission experiment with high lateral resolution were presented (see, e.g., Fig. 1), opening up new opportunities for the field of photoemission techniques. Lateral resolution could be achieved thanks to the use of high-brightness synchrotron radiation sources such as the undulators—which enhanced the signal-to-noise ratio. In the subsequent years, photoemission spectromicroscopy in different forms expanded becoming a leading subdomain of photoelectron spectroscopy.

One important aspect of this evolution was the impact on the life sciences. Without lateral resolution, photoelectron spectroscopy had been almost useless in biology, biophysics, and the medical research. Spatial dimensions such as the size of cells and cell components determine, in fact, the minimum spatial resolution required to provide meaningful information in these domains. Before the late 1980s, photoelectron spectroscopy was, as mentioned, very far from such resolution levels.

After the advent of photoelectron spectromicroscopy, photoemission-based probes became instead quite important in biology and medical research. They provided, in fact, very valuable microchemical information without requiring extensive sample preparation and the consequent risk of artifacts. However, photoelectron spectromicroscopy requires ultrahigh vacuum and this constitutes a limitation in biological applications.

Two approaches to photoelectron spectromicroscopy

There exist basically two approaches to achieve lateral resolution in a photoemission technique (Fig. 2). In the first case, the primary photon beam is focused into a small sample area and photoelectrons are produced only from that region. This approach is used in two complementary data-taking procedures.

In the first case (Fig. 2a), the photon beam is kept in a constant position on the sample surface and photoemission spectra are taken from that small spot. In the second case (Fig. 2b), the focused beam is scanned on the sample surface (or, more practically, the sample is scanned with respect to the beam) while photoelectrons are collected for a constant set of parameters—in particular a fixed energy. This gives two-dimensional photoemission intensity “images.”

Consider (Fig. 3) the case in which the focused spot is scanned while the collected photoelectron energy corresponds to photoelectrons excited from a core level of a given element. The photoemission intensity roughly corresponds to the concentration of that element. Therefore, the “images” are two-dimensional maps of the chemical composition at a microscopic scale.

Furthermore, a core-level energy changes slightly depending on the oxidation state of the element. Therefore, by fine-tuning the collected photoelectron energy one can obtain chemical maps of a given element in different chemical environments. Since photoelectron spectromicroscopy has the high surface sensitivity typical of nearly all photoemission experiments, such chemical

Fig. 1 “MAXIMUM,” one of the first photoelectron spectromicroscopy instruments, realized at the University of Wisconsin Synchrotron Radiation Center by a team led by Franco Cerrina (see Margaritondo G., Cerrina F. (1990) Overview of soft-X-ray photoemission spectromicroscopy. *Nuclear Instruments and Methods* A291: 26–35).

Fig. 2 The two implementation modes of photoelectron spectroscopy: in (a) the lateral resolution is achieved by focusing the X-ray photon beam. In (b) the resolution is produced by an electron lens system.

Fig. 3 Chemical microanalysis with the photon-focusing mode of photoelectron spectroscopy. The photoelectron detector is tuned to a kinetic energy K corresponding to the photoelectron emission from a core level of a given chemical element. This energy is above the vacuum level, which is the minimum energy to leave the sample. The corresponding photoemission intensity map reveals the presence and spatial distribution of the element.

maps correspond to the region near the sample surface—and provide extremely valuable information on surface processes including catalysis, corrosion and passivation.

The second approach to photoelectron spectroscopy (Fig. 2b) does not require focusing the photon beam. Lateral resolution is achieved instead by processing the emitted photoelectrons with an electron–optical system similar to an electron microscope.

Several years of practical experience demonstrated that the two approaches have advantages and disadvantages with respect to each other. In essence, they are largely complementary.

Practical implementation: Photon-focusing approach

Focusing photon beams is a major technical problem. The photons must have sufficient energy to enable electrons inside the solid to overcome the surface energy barrier and become photoelectrons. The photon energy falls in the ultraviolet range or above.

Furthermore, the energy of the photons must be sufficient to extract photoelectrons from the core levels of relevant chemical elements. The corresponding photon energies range from the vacuum ultraviolet to the X-rays.

Focusing is a relatively easy task only in a small portion of this spectral range, corresponding to its lowest photon energies (a few eV). For higher photon energies, it is a very difficult task.

There are three main reasons: (1) solid materials absorb photons in a large portion of the vacuum ultraviolet and soft-X-ray ranges, making it impossible to use transmission optical devices similar to optical lenses. (2) Hard X-rays can travel through solid materials, but the refractive index is very close to that of vacuum ($n \approx 1$), drastically limiting the effectiveness of refractive focusing devices. (3) The reflection of X-rays is extremely weak except for near-grazing incidence, and this tendency becomes stronger when the wavelength decreases. This limits the effectiveness of focusing by reflection except at extreme grazing incidence.

Effective technical solutions for these problems have been conceived and implemented. Fig. 4 shows a series of widely used X-ray-focusing devices suitable for several spectral domains.

Focusing mirrors

Mirrors can provide X-ray focusing as long as the angle of incidence is close to grazing incidence. This, however, complicates the fabrication processes and makes them quite expensive. The surface profile must, in fact, meet stringent requirements over a large area.

Fig. 4 Different X-ray focusing devices. (a) A single cylindrical, grazing-incidence mirror (left) focuses only in one direction, whereas (right) a combination of two such mirrors (Kirkpatrick–Baez lens) provides bidirectional focusing. (b) A Schwarzschild objective is formed by a convex spherical lens and a concave spherical lens, with nongrazing-incidence reflection enhanced by multilayer coatings. (c) A Fresnel zone plate (FZP). (d) (Left) a single biconcave refractive lens for hard-X-rays, and (right) a compound refractive lens (CRL).

The focusing surface can be toroidal, parabolic, or spherical (with some degree of aberration). Machining such surfaces with the required accuracy is technically difficult. It is also possible to use cylindrical surfaces that are easier to fabricate (e.g., by bending the mirror), but focus only in one direction. Bidirectional focusing requires, therefore, a pair of mirrors combined together in a “Kirkpatrick–Baez” device (Fig. 4a, right).

Schwarzschild objectives

These devices (Fig. 4b) focus visible light as well as X-rays, and this facilitates the alignment of the optical system. The lens is the combination of two reflecting spherical surfaces. Note that the reflection is not at grazing incidence, and this could sharply limit the throughput.

The problem can be solved by a suitable multilayer coating that enhances the reflection. The corresponding technology is, however, quite complicated. Furthermore, these lenses can only work in a limited spectral range that is typically located at photon energies below 100 eV. Even with these limitations, the Schwarzschild objectives did play a significant role in the development of photoelectron spectromicroscopy.

Fresnel zone plates

The Fresnel zone plates (FZPs) are widely used as focusing devices in different spectral ranges. As schematically illustrated in Fig. 4c, the working principle is based on the interference of rays passing through a series of alternating transmitting and blocking circular zones. The blocking zones are supported by a very thin substrate that allows a reasonable transmission of the X-ray beam.

The main difficulty in fabricating FZPs for X-rays is caused by the size of the zones. Their radial thickness decreases from the center to the periphery of the plate. Furthermore, the size decreases as the wavelength decreases. For X-ray wavelengths, the outermost-zone size is of the order of hundreds of angstroms. Therefore, the fabrication process requires sophisticated—and expensive—electron-beam lithography techniques. These problems notwithstanding, FZPs are now extensively used in X-ray microscopy and spectromicroscopy.

Refractive lenses and compound refractive lenses

For hard X-rays, the difficulties related to the limited transmission become progressively less important as the wavelength decreases—and it is possible to use refractive lenses. There exist, however, a significant difference between the refractive lenses for visible light and those for X-rays. The refractive index for X-rays is smaller in a material than in vacuum, whereas the contrary is true for visible light. An X-ray focusing lens, therefore, is not biconvex but biconcave (Fig. 4d).

As already mentioned, the refractive index differences between a material and vacuum are extremely limited. As a consequence, the focal length of a single biconcave refractive lens would be unreasonably large. The solution is provided by a series of lenses in the form of spherical cavities created inside a block—as also shown in Fig. 4d, right. Such a device is known as a “compound refractive lens” or CRL.

Fig. 5 Schematic experimental setup of a photoelectron emission microscope (PEEM) for the second mode of photoelectron spectromicroscopy.

Fig. 6 Left: primary photoelectrons are emitted with an energy K (above the vacuum level) corresponding to the initial energy in the solid plus the photon energy, without losses. Right: a secondary photoelectron loses part of its energy, typically through multiple losses, while traveling through the sample and before leaving it. The partial yield (PY) mode of photoelectron spectroscopy and spectromicroscopy is based on the detection of secondary photoelectrons.

Practical implementation: Electron-optics approach

Fig. 5 shows a typical electron-optics system for the implementation of this second approach to photoelectron spectromicroscopy. The standard name for this type of instrument is “photoelectron emission microscope” (PEEM).

Without photon focusing, it becomes easier to perform photoemission techniques that require changing the photon energy, which influences the focusing mechanisms. The most frequent way to use a PEEM is to perform “partial yield” (PY) measurements with high lateral resolution. A PY experiment is implemented by taking the intensity of the “secondary” photoelectrons as a function of the photon energy—see Fig. 6.

The secondary photoelectrons are the low-kinetic-energy electrons emitted from the sample after a loss of energy with respect to the of their excitation energy (the sum of the initial energy in the sample plus the photon energy). Such losses are typically due to multistep phenomena. The yield of secondary photoelectrons is proportional to the number of absorbed photons. Therefore, a PY curve closely resembles the plot of the X-ray absorption spectrum as a function of the photon energy.

Note, however, that the PY technique is surface sensitive—although the surface sensitivity is not as high as for other photoemission techniques due to the low kinetic energy of the detected secondary photoelectrons. Therefore, a PY curve primarily reflects the absorption coefficient of the region near the surface rather than that of the bulk.

With a PEEM, PY curves can be taken from small sample areas. This is a very powerful way to explore the local elemental composition and other chemical properties. An X-ray absorption spectrum is dominated by the absorption threshold of the component elements in the specimen and reveals their presence and chemical status. This approach is particularly convenient when local chemical information must be rapidly obtained.

The technique is typically implemented by first taking overall images corresponding to the partial-yield intensity emitted from different sample areas with a fixed photon energy (or with a “white” photon beam). Such images reveal the overall micromorphology of the specimen. Then, specific areas are selected for a more detailed analysis and PY spectra are taken from them.

PEEM is not limited to the detection of secondary electrons. By selecting the detected electron energies to coincide with specific primary photoelectrons, one can in fact implement very interesting experiments yielding sophisticated information.

Selected examples and performances

Fig. 7 shows an early example of photoelectron spectromicroscopy in the photon-focusing mode. The spectra illustrate a core level (Ge3d) of a Ge film on a semiconducting GaSe substrate.

This particular system has been considered as a typical example of interface in which no chemical reaction takes place. On the contrary, spectra taken in different areas of the interface show clear differences, even in the presence of noise, providing evidence for local chemical reactions that were not visible in a photoemission spectrum without spatial resolution. Therefore, without lateral resolution photoelectron, spectroscopy can be misleading.

Fig. 7 An example of photon-focusing photoelectron spectromicroscopy result. Two spectra taken at two different spots of a thin Ge overlayer on a GaSe substrate reveal different Ge3d core-level peaks—putting in evidence totally unexpected local chemical reactions. Experimental data extracted from Almeida J., Vobornik I., Berger H., Kiskinova M., Kolmakov A., et al. (1997) Spectromicroscopic evidence of Ge-GaSe chemical reactions: Not a Schottky system. *Physical Review B* 55: 4899.

Fig. 8 One of the first applications of electron-optics photoelectron spectromicroscopy to biological specimens. The PEEM image shows a mice neuron culture. Experimental data extracted from De Stasio G., Hardcastle S., Koranda S.F., Tonner B.P., Mercanti D., Ciotti M.T., Perfetti P., Margaritondo G. (1993) Photoemission spectromicroscopy of neurons. *Physical Review E* 47: 2117.

Fig. 8 shows an example of electron-optics photoelectron spectromicroscopy obtained with a PEEM operating in the PY mode. Note that the experiment concerns a biological sample: the PEEM technique is in fact particularly suited for studies in the life sciences and in medical research.

Resolution and sensitivity

The most relevant performances for photoelectron spectromicroscopy are the spatial resolution and the sensitivity to trace elements. Concerning lateral resolution, for both approaches to photoelectron spectromicroscopy it is necessary to distinguish between the “system” (optical or electron–optical) resolution and the practical level that can be obtained while performing real experiments.

The final resolution is, in fact, also limited by practical factors such as the signal level. Consider for example the comparison between the resolution delivered by an electron optics system used as an electron microscope and the corresponding resolution when the system is used for PEEM. In the first case, the lateral resolution reached long ago the nanometer level. But the spectromicroscopy resolution is worse because of the need for a reasonable signal-to-noise ratio.

Likewise, X-ray focusing devices can deliver in principle excellent resolution levels, but the practical resolution in spectromicroscopy is more limited. Consider for example a Fresnel zone plate: its optical resolution depends on the size of the outermost zone and can reach the nanometer level. However, the spectromicroscopy resolution although at the nanometer level, is typically limited to several nanometers.

Note that, the practical lateral resolution in a spectromicroscopy experiment is the result of a compromise between conflicting requirements. For example, lateral resolution can be reduced in order to achieve the required energy resolution while keeping the signal-to-noise ratio at a reasonable level. Achieving a sensible compromise is essential for a good use of spectromicroscopy, and cannot be handled with automated procedures.

Chemical sensitivity is an important point for spectromicroscopy. In a normal photoemission experiment without lateral resolution, the minimum detectable relative atomic concentration is 0.01–0.001. This is, of course, the local concentration in the near-surface region probed by photoemission. If the minority species is concentrated in that region, the equivalent relative concentration limit for the entire specimen is much lower.

Spectromicroscopy analyzes areas much smaller than $\approx 1 \text{ mm}^2$. If the minority species is not homogeneously distributed, by focusing on high-concentration areas the equivalent detectable concentration limit can be significantly lowered.

Recent developments

Photoelectron spectromicroscopy has become a standard technique for microchemical analysis. Spectacular performance improvements have been achieved in recent years. The primary factor has been the boost in the quality of the X-ray sources.

Several storage rings used as synchrotron radiation sources have been recently modified adopting new magnet lattices. This enabled them to reach the “diffraction limit” for most or all of their emission spectrum. The corresponding increases in brightness and coherence are by orders of magnitude. This progress directly translates into better performances in spectromicroscopy.

Also spectacular has been the impact of the X-ray free electron lasers. These devices are still rare but their number is expanding. And their performances are truly exceptional: a peak brightness exceeding that of storage rings by several orders of magnitude and a pulse duration of femtoseconds or less.

This opens the door to the analysis of many important phenomena in the same time scale. Therefore, photoelectron spectromicroscopy is becoming a fast time-resolved technique with an outstanding potential for new applications in many different disciplines.

Conclusion

By combining spatial resolution with spectroscopy analytical capability, the different types of spectromicroscopy techniques became very powerful instruments for materials sciences and biomedical research. This is particularly true for photoelectron spectromicroscopy in its different modes of implementation within their two main classes—photon focusing and electron optics. The applications are now further expanded by the advent of new and very advanced X-ray sources such as the free electron lasers and ultrabright storage rings.

Abstract

The scanning electron microscope is widely used in condensed matter physics research for providing nano-scale topographic images of material surfaces. This chapter introduces the subject of scanning electron microscopy, mostly in terms of describing the basic principles behind how the scanning electron microscope (SEM) instrument functions and its main figures of merit, such as image resolution and signal-to-noise. The chapter emphasizes how the overall performance of a scanning electron microscope is critically dependent on a variety of different factors, such as the quality of its electron source, the low aberration design of its objective lens, and primary beam-specimen interaction effects.

Introduction

The scanning electron microscope (SEM) is an indispensable research and development tool in the subject of condensed matter physics. It is the most widely used instrument for examining the surface topography and morphology of bulk materials on the nanoscale. It is capable of routinely obtaining an image resolution of 1–2 nm on a variety of different materials, a factor of around 200 times better than the spatial resolution of conventional optical microscopes.

In the category of electron microscopes, the SEM is smaller, cheaper, and more accessible than a transmission electron microscope (TEM) or a scanning transmission electron microscope (STEM). Its specimens require much less preparation and its images are much easier to interpret. These advantages come from the fact that it functions by detecting reflected/scattered electrons from bulk specimens rather than relying on an electron beam propagating through a thin specimen (nm thick), as is the case with transmission electron microscopes. These advantages come at the price of its overall image resolution being around an order of magnitude poorer than those that can be obtained by a TEM or a STEM. In general, however, the SEM plays a complementary role to transmission electron microscopes. It provides information on a sample's surface and its composition, while a TEM or STEM acquires information on the inner structure of the sample, such as crystal structure.

Several companion analytical tools have been developed for the SEM that transform it into a powerful material analysis tool, taking it beyond a purely topographical imaging mode of operation. The energy dispersive X-ray (EDX) spectroscopy technique for instance, is used in the SEM to capture atomic transitions that emit characteristic X-rays, enabling it to carry out quantitative material analysis. The electron backscatter diffraction technique (EBSD) inside the SEM is routinely used to provide a material's crystal structure, orientation, phase, and strain information. SEMs have also been developed to operate with a gaseous environment inside the specimen chamber, which provides the option of using wet samples and uncoated non-metallic samples. These SEMs are known as environmental SEMs (ESEMs). There have also been many other advances, such as the inclusion of a gun monochromator unit to lower the primary beam energy spread, further improving the electron optics of SEMs. However, the focus of this chapter will be mainly to describe the basic principles upon which a SEM functions, give its main figures of merit, provide some sample high resolution experimental images, and highlight some promising avenues for future development.

The development of the SEM instrument took place approximately between the years 1925–65, shortly after which the first commercial SEM was launched (McMullan, 1995), and since then, the instrument has undergone many technological improvements (Khursheed, 2011; Goldstein et al., 2017; Brodusch et al., 2018). In particular, over the last few decades, the technique of low voltage scanning electron microscopy (LVSEM) has overcome many traditional limitations. The LVSEM technique has been able to reduce the energy with which the primary electron beam strikes the specimen while at the same time keeping its probe size small by taking advantage of various electron optical innovations, and thereby greatly improving its overall image resolution capability. LVSEMs also have higher signal yields, a smaller beam/specimen interaction volume, greater surface information, and are able to

minimize charging effects while inspecting non-conductive specimens. This chapter will describe the SEM instrument mainly in terms of its transformation into the LVSEM.

SEM basic principles

The SEM functions by raster scanning a focused beam of electrons over the surface of a bulk specimen, as shown in Fig. 1a. The beam of electrons, usually referred to as the primary beam, is generated and accelerated to energies from 0.5 to 30 keV inside an electron source unit located at the top of the SEM. The electron source is rotationally symmetric and is designed to emit a round shaped primary beam. The primary beam is emitted with an effective source diameter, energy spread and brightness, and is then subsequently demagnified and focused by a series of electron optical lenses in order to produce a primary electron beam probe of nano-size dimensions that is scanned over the specimen surface.

The number of electron optical lenses required in the column depends on the effective source diameter of the electron source. Fig. 1a depicts two demagnifying lenses, a condenser lens placed just below the electron source, and an objective lens placed just above the specimen. This configuration is widely used for the Schottky electron source (SE), which emits electrons by using the principle of thermal field emission (Bronsgest, 2014). The amount of demagnification applied to the primary electron beam, M_B , can be estimated by using simple first-order optics principles using the focal spot distances P_1 , Q_1 , P_2 , and Q_2 shown in Fig. 1a. The demagnification factor M_B is given by $(Q_1/P_1) \cdot (Q_2/P_2)$. It can also be obtained in terms of the initial source semi-angle α_s ratio with the final beam probe semi-angle α_p , by α_s/α_p . The source spot size needs to be demagnified by a factor of only 5–15 for the Schottky electron source, but for conventional heated tungsten wire electron sources (TE), demagnification factors can range up to 10,000 (Oatley, 1975).

A final circular aperture filters out wide-angle electrons in the primary beam before it enters the objective lens, and a scan unit, usually consisting of magnetic coils, performs the deflection action of raster scanning the primary beam over the specimen surface. The purpose of filtering out wide-angle electrons in the primary beam is to reduce objective lens aberration effects, ensuring that the primary beam electrons striking the specimen have low semi-angles (down to a few millirad) and that they travel close to the objective lens rotational axis of symmetry (within tens of microns). The rotational axis of symmetry of all electron lenses in the SEM is often simply referred to as the SEM's optical axis.

On striking the specimen, the primary beam generates scattered electrons that leave the specimen surface over a wide range of angles and energies. The low energy scattered electrons, known as the secondary electrons (SEs), are attracted on to an electron detector located away to one side of the axis, below the objective lens. The SE energy range is usually defined from 0 to 50 eV, where the upper limit is an arbitrary number having no physical importance. The number of SEs captured by the SE detector is strongly modulated by the specimen's surface topography, as shown in Fig. 1b, which is then translated into image brightness variations on a display monitor. The SE detector signal is amplified and synchronized to the scan deflector unit, so that each scanned point on the specimen corresponds to a single point in the SE display image.

Fig. 2 Electron primary beam-specimen scattering characteristics. (a) Interaction volume and the electron/photons leaving the specimen surface. (b) Energy distribution of the scattered electrons leaving the specimen surface.

The size of the primary beam focused on to the specimen surface, the probe diameter, d_p , depends not only on the overall demagnification of beam, M_B , but also on the objective lens aberrations. The probe diameter d_p is an important parameter limiting the final SE image resolution, and together with the final semi-angle α_p , it also determines the image depth-of-focus, the specimen depth over which points in the SEM image still appear to be in focus, as illustrated in the schematic diagram shown in Fig. 1c. SEM images have the desirable feature of having a relatively large depth of focus compared to optical microscopes, an advantage which comes from them having relatively small final semi-angles (in the several milli-rad range).

After the primary beam strikes the specimen surface, it loses energy by undergoing a series of multiple collisions inside the specimen, which are largely confined to a balloon shaped region known as the interaction volume, as shown in Fig. 2a. The complex set of events that take place inside the interaction volume generate a cascade of electrons and photons, some of which are able to leave the specimen surface. The lower energy scattered electrons that escape from the specimen surface, the SEs, typically come from nanometer size depths, while the higher energy scattered electrons, the backscattered electrons (BSEs), are typically generated from depths that range from tens to hundreds of nanometers. Since the number of emitted BSEs rises with specimen atomic number, a BSE detector is commonly placed under the objective lens in order to obtain a material contrast image. The BSE image is only capable of providing a map of qualitative material/density changes, and its image resolution is in general significantly poorer than the one provided by the SE image. For these reasons, the BSE image is usually used together with the SE image in order to provide extra material information about the specimen.

Although Auger electrons are generated from even shallower depths inside the specimen than the SEs, they are generally masked by the presence of a nanometer thick hydrocarbon contamination layer. This contamination layer comes from the interaction of the primary beam with the specimen surface and residual gas molecules inside the high vacuum (HV) specimen chamber (10^{-6} – 10^{-5} Torr). In practice, the only detectable Auger electrons inside a SEM specimen chamber are those that are generated from within the contamination layer (carbon peak). At micron depths below the specimen surface, characteristic X-rays created from atomic transitions are emitted, and they are used by the energy dispersive X-ray (EDX) spectroscopy technique to perform quantitative material analysis, most commonly used to identify the different types of materials present in the sample. At even lower depths, photons emitted in the 200–800 nm wavelength range are used by the Cathodoluminescence technique in order to provide information about trace elements contained in mineral samples or capture the presence of mechanically induced defects in crystals.

The scattered electrons emitted from the specimen surface have a wide range of energies, as shown in Fig. 2b. The lower part of the distribution is dominated by the SE energy distribution, whose peak typically lies in the 1–2 eV range. In the higher part of the scattered electron energy distribution, there is the BSE peak. Elastically scattered BSEs, known as low loss BSEs, make up the upper part of the electron energy spectrum close to the primary beam energy. Since low loss BSEs emanate from nanometer size depths

Fig. 3 Schematic drawing of raster scan area on the specimen and its corresponding image on the SE signal monitor display.

inside the specimen, they can be used to provide a way of improving the BSE image resolution (Luo and Khursheed, 2007). Detection of low loss BSEs in some SEM columns is achieved by placing high pass energy filters placed in front of the BSE detector.

It is important to note that the SEM does not function like a conventional optical microscope, where a transparent specimen is illuminated by a collimated light beam, and where the subsequent transmitted/scattered light propagating along an optical axis is then magnified into an image by a series of projection lenses. The TEM functions in this way, but not the SEM. Instead of projecting and magnifying a transmitted electron beam into an image, the SEM demagnifies an electron beam coming from an electron source into a nanosize probe which is raster scanned over the surface of the specimen, and its final image is formed from reflected/scattered electrons that leave the specimen. Unlike the parallel action of a TEM, where points from a region of the specimen are simultaneously projected and focused into a set of corresponding points in a final image, an SEM image is formed one point at a time, in a sequential way, similar to how the early generation of cathode ray tubes formed their images, or how an image is formed on a radar screen. In fact, historically, both cathode ray tubes and the invention of radar greatly influenced the way the SEM was invented and subsequently developed (Smith, 1997).

Fig. 3 shows the area of scan on the specimen's surface created by electronic deflection of the primary beam and its corresponding image displayed on the SE monitor. The field of view is given by the area scanned on the specimen surface, (X_S , Y_S), while the image magnification M_I is given by the ratio of the image size displayed on the SE monitor, (X_D , Y_D), to the scan area size on the specimen, X_D/X_S or Y_D/Y_S . It is important not to confuse the electronic image magnification M_I , with the primary beam spot demagnification factor, M_B . The magnification displayed on the monitor screen refers to the electronic image magnification M_I , while the primary beam demagnification factor is not usually given explicitly. A relative indication of its value can be inferred by a "spot size parameter" on the condenser lens settings.

Fig. 4 Monte Carlo simulation of primary electrons striking a silicon sample at energies 1, 5, 10, and 20 keV.

The best achievable image resolution of an SEM is limited by a variety of different factors. Apart from electron optical demagnification/focusing considerations, there are also primary beam-specimen interaction effects. An illustration of how primary beam-specimen interaction effects can limit the spatial resolution of an SEM is shown in Fig. 4, which depicts Monte Carlo simulation results of a primary beam scattering inside a silicon specimen at different primary beam landing energies. The scattering region, approximately equivalent to the interaction volume, effectively generates areas of SE/BSE emission on the surface of the specimen. The size of these emission areas can easily exceed the focused primary beam probe size, and therefore limit SEM image resolution. The Monte Carlo simulations shown in Fig. 4 predict that at a landing energy of 1 keV, the interaction volume is tens of nanometers wide. At 5 keV, the interaction volume is predicted to span hundreds of nanometers. Beyond 10 keV, the simulated interaction volume reaches micron dimensions. Historically, due to poor electron optical performance at low primary beam voltages (<5 kV), the first generation of SEMs were usually operated with primary beam energies in the 5–30 keV range. The simulations shown in Fig. 4 help explain why the first generation of SEMs could only achieve image resolutions in the submicron to micron range.

As already mentioned, significant improvements to SEM image resolution were made when it became possible to lower the landing energy of the primary beam to landing energies of 1 keV or lower, without significantly enlarging the primary beam probe size. Most modern SEMs today function in this way, in the low voltage SEM mode of operation (LVSEM). LVSEM relies on technological advances made in the production of electron detectors, and improvements made in the design of electron sources and objective lenses.

Another advantage of LVSEMs is that they can minimize primary beam induced charging effects while observing non-conductive specimens. The first generation of SEMs needed to sputter non-conductive specimens with a nanometer thick layer of gold or carbon in order to suppress the charging effect. Other advantages of LVSEM over conventional SEMs include them having higher signal yields and that they provide a greater amount of surface information. It is now possible for SEMs to operate with nanometer image resolution on a wide variety of different specimens. LVSEMs are finding an increasing number of applications in subjects such as biology and chemistry which involve observing organic samples directly.

When inspecting a specimen by an SEM, it is important to strike the right balance between acquiring adequate signal-to-noise and minimizing the effects of surface contamination. The main source of noise in the output image comes from shot noise in the primary beam, which for a sufficiently large number of detected electrons has an approximate normal distribution. In most modern SEMs, tens of pA primary beam current in tens of seconds image acquisition time can in principle provide adequate signal-to-noise ratios, but in practice, whether the final captured image is acceptable or not depends on the rate at which the specimen surface carbon contamination layer builds-up.

Contamination on the surface of a specimen is most severe when acquiring high resolution images. This is because high resolution imaging requires small fields of view, which for the same primary beam current and scan rate, leads to larger current densities being present at the specimen surface, and this creates conditions for a greater rate of contamination build-up. The compensating action of adjusting down the primary beam current or total acquisition time when capturing high resolution images partially helps avert this problem, but it can only be done within the constraints of obtaining an adequate output signal-to-noise ratio. For this reason, beam induced contamination is one of the main parameters that limit the ultimate image resolution of SEMs.

The other main beam-specimen interaction parameter limiting image resolution is the interaction volume. Although the interaction volume is made much smaller by operating in LVSEM mode, its finite size also plays an important role in limiting how good the image resolution in an SEM can be. The image resolution limiting role played both by beam induced contamination and the interaction volume helps explain why the same type of electron optical aberration correctors that have worked well for transmission electron microscopes (STEM/TEM) have not worked well for the SEM. Transmission electron microscopes form their output images from a primary electron beam that travels through a thin specimen, in which beam-specimen interaction effects played a relatively minor role compared to electron optical aberrations. In the SEM however, since the image is formed from reflected/scattered electrons that leave the surface of a bulk specimen, beam-specimen interaction effects are much larger, and are comparable in size or greater than the primary beam probe size. Although electron optical aberration correction techniques in the SEM can in principle reduce the primary beam probe to have sub-nanometer diameters, in practice, beam-specimen interactions cause the image resolution limit to be well over a nanometer. There are also inaccuracies caused by mechanical vibrations and electromagnetic interference. At a landing energy of 100 eV, the image resolution of an aberration corrected SEM was found experimentally to be around 2 nm on a test sample having gold particles on a carbon substrate, despite its probe diameter being predicted to be less than 1 nm (Cheng et al., 2019).

On non-conductive samples, there is also the local charging effect. Although LVSEMs are able to achieve an overall global charge balance on a variety of different non-conductive specimens, local charging inevitably occurs over nanometer distances on the specimen surface, and it can distort and deflect the primary beam probe, which in turn can degrade the overall achievable image resolution. This effect causes well known image distortions and resolution limitations in the context of using Critical Dimension (CD) SEM measurements on semiconductor specimens (Arat et al., 2019).

Electron optical figures of merit

The performance of an SEM is critically dependent on the type of electron source being used. The column optics is adjusted so that the projected size of the source on the specimen is small. The energy spread of electrons emitted from the electron source limits the resolution of the SEM at low voltages, and the final image quality depends upon how much current the gun can provide. There have been two types of thermionic sources, and two types of field emission sources used in commercially available SEMs so far.

In the category of thermionic electron sources, there is the tungsten hairpin wire source and the lanthanum hexaboride crystal (LaB₆) source. Both these electron sources form a real crossover point between the cathode and anode. They do this by employing an

extra electrode placed between the cathode and anode and biasing it more negatively than the cathode. A current is passed through the cathode and heats it to high temperatures so that electrons are emitted from the cathode surface. The electric field strength at the cathode surface is relatively low, and a negative space-charge cloud region consisting of slower moving emitted electrons forms in front of the cathode. The emission current settles to an equilibrium value limited by the formation of the space-charge cloud.

Field emission sources function by applying a high electric field between an anode electrode and a finely pointed cathode. The radius of curvature of the cathode tip can be as low as 100 nm and the electric field strength can be several V/nm. Electrons leave the cathode tip via quantum tunneling and do not form a real crossover, instead, they form a “virtual source,” which is found by projecting back the emitted rays from the anode plane. The virtual source position typically lies several nanometers behind the cathode electrode tip and ranges from a few to tens of nanometers in diameter. The Schottky electron source supplements its quantum tunneling action with some degree of cathode heating. Cold field emission (CFE) cathodes function at room temperature.

The brightness of an electron gun, β , is an important parameter that characterizes how much current it can provide. The brightness β is defined by

$$\beta = \frac{J}{\pi\alpha^2} \quad (1)$$

where J is the current density and α is the beam semi-angle at the cathode. For a given SEM column, the brightness has a constant value along the primary beam path. The current density at the cathode usually falls off sharply with increasing α . Since the brightness of a gun rises approximately linearly with the anode voltage (primary beam voltage V_p), it is sometimes quoted as the “reduced brightness,” β_R , where $\beta_R = \beta/V_p$.

The conservation of brightness along the optical axis provides a means for estimating the primary beam probe current at the specimen surface. If at the specimen, there is a projected source diameter of d_0 and semi-angle of α_0 , the primary beam probe current, I_p , is given by

$$I_p = \frac{\pi^2}{4} \beta d_0^2 \alpha_0^2 \quad (2)$$

The available probe current is directly proportional to the gun brightness. From this expression, it is clear that high probe currents cannot be obtained with small probe diameters (required for high resolution) and that a compromise between the two must be found. A minimum requirement on the probe current comes from inherent signal-to-noise limitations in the SEM detection/display system.

Each SEM electron source type varies in accordance with the amount of current it can produce, its effective projected size, its intrinsic energy spread, the stability of its emitted current, and its lifetime. Table 1 presents some typical values of these parameters. It should be noted that the values in Table 1 are only approximate, and that some of them depend on the primary beam voltage, such as brightness.

Although the traditional thermionic tungsten hairpin source has the lowest brightness and highest energy spread of all SEM electron sources types, it is reliable, relatively inexpensive, and well understood. For many SEM applications where high brightness and high spatial resolution is not required, and where stable high currents are needed, the thermionic tungsten filament may be used without loss of performance, and may, in fact, be the best choice. The LaB₆ source offers better performance than the tungsten hairpin filament, but it comes at the price of needing to provide a better vacuum level and is more complicated to install and maintain. In practice, the tungsten hairpin filament is much more widely used.

In the category of field emission electron sources, the tungsten cold field emission source has the highest brightness and lowest energy spread, but it faces many difficult technical challenges and is the least reliable of all electron sources for the SEM. It typically requires extreme UHV (XUHV) conditions in order to operate, and its cathode needs to be regularly joule-heated (flashed) every few hours in order to restore degradation of emission caused by the steady build-up of carbon contamination on the cathode tip surface. It also has the highest current instability of all SEM electron source types. For these reasons, although the Schottky electron source is worse from an electron optical performance point of view than tungsten cold field emission sources, it is the most widely used type of field emission source in SEMs.

Fig. 5 shows the kind of magnetic objective lens design that has been widely used in conventional SEM columns. The magnetic objective lens axis is rotationally symmetric, and its axis of symmetry defines the central optical axis for the primary electron beam. A current carrying coil energizes a magnetic circuit made of soft magnetic material, typically an alloy of iron, and a magnetic gap in

Table 1 Electron source performance comparison.

Source	Brightness (A/cm ² sr)	Lifetime (hours)	Source size	Energy spread ΔE (eV)	Current stability	Vacuum pressure (Pa)
Tungsten hairpin thermionic source	2×10^4 to 2×10^5	40–100	20–50 μm	1–3	1%	$<10^{-3}$
LaB ₆ thermionic source	10^6	200–1000	5–20 μm	0.5–2	1%	$<10^{-5}$
Schottky field emission source	10^7 – 10^8	>1000	15–30 nm	0.5	2%	$<10^{-7}$
Tungsten Cold field emission source	10^8 – 10^9	>1000	< 5 nm	0.2–0.3	5%	$<10^{-8}$

Fig. 5 Simulated on-axis magnetic field distribution $B_z(z)$ and flux distribution of a conventional Cambridge S100 SEM magnetic objective lens design.

the circuit creates the axial magnetic field region that focuses the primary electron beam on to the specimen. Fig. 5 shows the simulated flux lines of the Cambridge S100 objective lens design for a coil excitation of 1000 AT and its associated axial field distribution. The axial field peak field strength is 0.0836 Tesla, capable of focusing a 20 keV primary beam to a point 5 mm below the lower lens pole-piece. The focusing action, illustrated schematically in Fig. 5, comes from the radial variation in objective lens magnetic field intensity. The magnetic field intensity is a minimum on the axis, and it increases in strength radially out toward the pole-pieces. This field distribution causes electrons in the primary beam to rotate about the axis and exerts a radial force on them, pushing them toward the axis. The strength of the radial force increases with off-axis distance, applying a stronger force on the wider angle electrons and a weaker force on the near axis electrons.

The Cambridge S100 objective lens shown in Fig. 5 is an example of a “below-the-lens” design. The specimen in these types of objective lenses is placed in a field free region under the lens assembly. The distance from the specimen to the lens lower pole-piece is known as the working distance (WD), and is similar to the working distance between specimen and objective lens in conventional optical microscopes. Just as in optical microscopes, short focal lengths are required when operating in high magnification mode, which in turn, necessitates the use of short working distances. In practice, SEM columns that use below-the-lens objective lens designs achieve their highest image resolution by setting the working distance to its minimum possible value. Most conventional SEMs have an operational working distance range of around 3–30 mm.

Fig. 6 shows the kind of column lens design used in conventional tungsten hairpin filament SEMs. It consists of two magnetic condenser lenses and a magnetic objective lens. This is different to the Schottky electron source single condenser lens column design shown in Fig. 1a. An extra condenser lens in the case of the conventional tungsten hairpin filament SEM column is required, since the beam crossover size formed inside tungsten hairpin filaments is typically a thousand times bigger than Schottky electron source virtual source sizes.

In addition to limitations in electron optical performance that come from the electron source, objective lens aberrations also play a critical role. In order to keep the aberrations of the objective lens down to an acceptable level, a final aperture is used to filter out the wider angle electrons in the primary electron beam. The final aperture is usually positioned just above the objective lens, and its diameter is selected to keep the semi-angles of electrons reaching the specimen to be typically less than 5 mrad. Fig. 7 shows the kind of lens aberration effects that enlarge the primary beam probe size. They are similar to the kind of aberration effects that exist in optical microscopes.

Spherical aberration is caused by the objective lens over-focusing the wider angle electrons in the primary beam, as shown in Fig. 7a. They travel further off-axis than the narrower angle ones and experience a stronger focusing action acting on them, producing a spherical aberration spot radius r_{SP} which is proportional to the cube of the final semi-angle as follows,

$$r_{SP} = C_S(\alpha_P)^3 \quad (3)$$

where the constant C_S is defined to be the spherical aberration coefficient.

Chromatic aberration comes from the inherent energy spread of electrons in the primary beam. Higher energy primary beam electrons focus at focal points further down the axis than the lower energy primary beam electrons, as shown in Fig. 7b. The change in focal point position along the axis, Δz , varies linearly with relative energy spread, $\Delta E/E$, as follows,

$$\Delta z = C_C(\Delta E/E) \quad (4)$$

where the constant C_C is the chromatic aberration coefficient. In field free focusing regions, the chromatic aberration spot radius, r_{chr} , is given in terms of the final semi-angle α_P by, $r_{chr} = \Delta z \alpha_P$.

Fig. 6 Simulated ray tracing of the primary electron beam through a column having two magnetic condenser lenses and a S100 objective lens. (a) Axial field distribution. (b) Ray tracing of the primary beam, where the radial coordinate is exaggerated for reasons of scale.

Fig. 7 Schematic drawing illustrating primary electron beam on-axis focusing aberrations. (a) Spherical. (b) Chromatic. (c) Diffraction.

An aperture diffraction aberration spot is also produced at the plane of the specimen. This diffraction effect comes from the intrinsic wave nature of the electrons in the primary beam. As in light optics, the diameter of the diffraction aberration spot produced by a round aperture is $0.61 \lambda / \alpha_p$, where λ is the De Broglie wavelength and α_p is the final semi-angle. The diffraction spot size is taken from the first zero point of a zero order Bessel function radial diffraction distribution, as shown in Fig. 7c. The De Broglie wavelength of an electron beam in an SEM is related to the primary beam voltage V_p by, $\lambda = 1.226 / \sqrt{V_p}$, where the primary beam voltage is measured in volts and the wavelength is measured in nanometers. Using this formula, the wavelengths for a beam of electrons at 1 and 25 keV are 38.7 pm and 7.74 pm respectively. Although this wavelength is several orders of magnitude smaller than it is for say a visible light beam, the relatively small final semi-angles used in an SEM, in the mrad range, increases the diffraction spot diameter of the primary beam probe to nanometer sizes, making it comparable in size to the spot diameters produced by spherical and chromatic aberration.

A convenient way of estimating the spatial resolution of a SEM column design is to use the Barth-Kruit root-power-sum formula (Barth and Kruit, 1996), which approximates it to be equivalent to the final probe diameter containing 50% of the primary beam current. This formula has been found to agree well with the more exact wave optical approach, and is widely used to calculate the spatial resolution of an electron objective lens. It uses the electron source parameters of energy spread ΔE , source brightness β , objective lens on-axis spherical aberration coefficient C_S , chromatic aberration coefficient C_C , primary beam current I , landing energy E , beam wavelength λ , and beam final semi-angle α_p . The Barth-Kruit root-power-sum formula for the probe diameter d_p is given by,

$$d_p^2 = \left[\left(d_{sp}^2 + d_{df}^2 \right)^{\frac{1.3}{4}} + d_G^{1.3} \right]^{\frac{2}{1.3}} + d_{chr}^2 \quad (5)$$

where, $d_{sp} = \left(\frac{1}{2} \right)^{5/2} C_S \alpha_p^3$

$$d_G = \left(\frac{2}{\pi} \right) \left(\frac{I}{\beta} \right)^{1/2} \frac{1}{\alpha_p}$$

$$d_{chr} = 0.34 C_C \frac{\Delta E}{E} \alpha_p$$

$$d_{df} = 0.54 \frac{\lambda}{\alpha_p}$$

Aberration coefficients for objective lenses can be found directly from numerical ray tracing methods, or indirectly by a perturbation method that uses the axial field distribution (Khurshheed, 1999). For the Cambridge S100 objective lens shown in Fig. 5 operating in LVSEM conditions, where the lens strength is adjusted to focus a 1 keV beam on to a specimen located at a working distance of 5 mm, the focal length, f , and aberration coefficients, C_S and C_C were simulated by numerical ray tracing to be, $f = 15.69$ mm, $C_S = 30.6$ mm, and $C_C = 13.29$ mm (Khurshheed, 2011). Fig. 8 uses these optical parameters to plot the corresponding probe diameter/probe current dependence using the Barth-Kruit formula (Eq. 5) for both thermionic tungsten hairpin filament (TE) and Schottky (SE) electron sources. The TE source here is assumed to have a brightness of $2 \times 10^4 \text{ Acm}^{-2} \text{ sr}^{-1}$ and an energy spread of 2 eV, while the SE source is assumed to have a brightness of $10^7 \text{ Acm}^{-2} \text{ sr}^{-1}$ and an energy spread of 0.5 eV. For every probe current value, the final aperture radius is varied in order to obtain the optimal semi-angle which minimizes the probe diameter.

Fig. 8 Simulation of the probe diameter/current dependence of a conventional Cambridge S100 SEM objective lens design using thermionic tungsten hairpin filament (TE) and Schottky (SE) electron sources. The working distance is set to 5 mm for a primary beam energy of 1 keV, and the simulated focusing on-axis aberrations are, $f = 15.69$ mm, $C_S = 30.6$ mm, and $C_C = 13.29$ mm. The TE source is assumed to have a brightness of $2 \times 10^4 \text{ Acm}^{-2} \text{ sr}^{-1}$ and an energy spread of 2 eV, while the SE source is assumed to have a brightness of $10^7 \text{ Acm}^{-2} \text{ sr}^{-1}$ and an energy spread of 0.5 eV.

The simulated probe current-diameter performance shown in Fig. 8 illustrates why the early generation of SEMs, which used a thermionic tungsten hairpin filament combined with a below-the-lens objective lens design, were seldom operated in LVSEM mode. At a primary beam energy of 1 keV, the simulated TE source S100 objective lens simulated probe diameter varies from 50 to 90 nm over the probe current range of 10–100 pA, while the probe diameter of the SE emission source for the same operating conditions stays around 10 nm. The better simulated performance for the SE electron source comes from it having a much higher brightness and lower energy spread than the TE electron source. The image resolution of SEMs that use TE sources is mostly probe current limited when operated in LVSEM mode, while the image resolution of field emission SEMs is generally objective lens aberration limited.

Figs. 9b–d presents schematic diagrams of various LVSEM objective lens design improvements that have been made over the last few decades. Unlike the conventional below-the-lens objective lens layout, shown in Figs. 5 and 9a, they function by either immersing the specimen in a magnetic field, shown in Fig. 9b, or by applying a strong decelerating electric field above the specimen, shown in Fig. 9c, or by combining a decelerating electric field with a magnetic immersion field, shown in Fig. 9d. These objective lens design improvements are known as LVSEM “in-lens” designs since they involve placing the specimen inside objective lens electric/magnetic focusing fields. Another important difference is that since the specimen is now placed inside a lens field distribution, the emitted SEs travel back up through the objective lens bore and are detected either inside the lens assembly or above it (Figs. 9b–d). In conventional objective lens designs, SEs are always detected below the lens assembly (Figs. 5 and 9a).

The LVSEM layout depicted in Fig. 9b uses the magnetic field created around a single conical shaped pole-piece to define a sharply varying field distribution under which the specimen is placed. This kind of lens is sometimes referred to as single-pole lens since its primary beam focusing field is created around only one pole-piece. It is also known as a semi-in-lens design, in order to distinguish it from the kind of full magnetic immersion lens designs used in TEMs, in which the specimen is inserted into a small magnetic gap region between two pole-pieces.

Fig. 10 shows the simulated flux lines of a typical single-pole magnetic semi-in-lens objective lens design. A sharply varying axial magnetic field is projected down into the region immediately below the inner conical pole-piece. The specimen needs to be positioned close to the pole-piece tip with a working distance of only a few millimeters (1–3 mm), so that the primary beam can be

Fig. 9 Different types of objective lens designs used for the SEM. (a) Conventional lens where specimen is placed in a field-free region below the objective lens pole-pieces. (b) Magnetic semi-in lens where the specimen is immersed in a magnetic field region below the lens pole-pieces. (c) Retarding field design using a booster electrode (9 kV) combined with a conventional magnetic objective lens. (d) Retarding field design using negative specimen bias (–9 kV) combined with a magnetic semi-in-lens.

Fig. 10 Simulated flux lines of a single-pole magnetic semi-in-lens objective lens design.

focused on to the specimen with millimeter size focal lengths. This type of objective lens design was reported over three decades ago. For a single pole-piece with an outer slope angle of 45° having an overall pole diameter of 5 mm and a bore diameter of 3 mm, set to focus a 1 keV primary beam on to a specimen located at a working distance of 2.5 mm, its on-axis focusing aberrations were simulated to be $f = 1.8$ mm, $C_s = 1.5$ mm, and $C_c = 1.3$ mm (Shao and Lin, 1989). These lens aberration coefficients are around an order of magnitude smaller than the on-axis aberrations of conventional below-the-lens designs for the same operating conditions.

In the case of the LVSEM design shown in Fig. 9c, a booster electrode (9 kV) keeps the primary beam energy high as it travels down the column (10 keV), and a 0 V specimen retards the beam to have a landing energy of 1 keV. The primary beam is slowed down sharply just before it strikes the specimen, over a distance of only a few millimeters. Since the primary beam travels through most of the magnetic focusing field region at a high energy and is slowed down only in the tail end part of its distribution, the lens on-axis aberrations and focal length are considerably smaller than the case where there is no retarding field. An LVSEM column using the kind of layout shown in Fig. 9c, decelerating a 10 keV primary beam energy down to a landing energy of 1 keV, was reported to have lower on-axis aberrations than corresponding magnetic objective lens designs for LVSEM applications. Frosien et al. for instance, presented a retarding field objective lens design having a C_s less than 3 mm and C_c around 1 mm for a landing energy of 1 keV, in which the specimen was not immersed in a strong magnetic field (Frosien et al., 1995). Unlike most LVSEM columns using magnetic semi-in-lens designs, their objective lens design had the advantage of being able to image magnetic specimens.

From an electron optical point of view, the lowest focusing aberrations are produced by an LVSEM objective lens design that uses a combination of both a magnetic immersion field and a decelerating electric retarding field, such as the lens design shown in Fig. 9d. In this case, a 10 keV primary beam travels down a 0 V column, and is retarded to have a landing energy of 1 keV on a specimen that is biased to -9 kV. This lens design achieves the same strong retarding field electric field action as the retarding field design shown in Fig. 9c, but has the desirable feature of not having to use a booster electrode in the column. At the same time, the specimen is placed in a semi-in-lens magnetic field distribution.

Fig. 11 shows simulated field distributions of a mixed field semi-in-lens LVSEM design based on the one reported by Beck et al. (1995). This lens design uses a 9 kV booster electrode to create a retarding electric field while at the same time is immersing the specimen in a magnetic field. The magnetic field projects down from a large radial gap in the magnetic circuit, as shown in Fig. 11c. Fig. 11b shows the axial electric potential distribution of its decelerating electric field. This type of deceleration action, as well as the semi-in-lens magnetic immersion field distribution, significantly lowers the on-axis aberrations of the objective lens. Beck et al. reported simulated focusing on-axis aberration parameters of $f = 4.24$ mm, $C_s = 0.77$ mm, $C_c = 0.62$ mm for a 10 keV primary beam retarded down to a landing energy of 1 keV at a working distance of 5 mm (Beck et al., 1995).

Fig. 12 presents the probe diameter vs probe current dependence using the Barth-Kruit formula of the three main objective lens designs discussed so far operating with a Schottky electron source at a landing energy of 1 keV. Simulated on-axis aberration parameters are used for the conventional S100 design operating at a working distance of 5 mm, the single-pole magnetic semi-in-lens design operating at a working distance of 2.5 mm, and the mixed field semi-in-lens design operating at a working distance of 5 mm. The results support the general point that the image resolution of FE SEMs for LVSEM applications is mainly aberration limited, and not probe current limited like TE source SEMs (see Fig. 8). The probe diameter for the lens designs shown in Fig. 12 does not change significantly with primary beam current. The probe diameter of the mixed field semi-in-lens design is around a factor of five times smaller than the probe diameter of the conventional S100 objective lens, and about 1 nm smaller than the magnetic semi-in-lens design.

Fig. 13 shows the kind of probe diameter/probe current improvement that can be expected by using a CFE source in combination with semi-in-lens LVSEM designs. The CFE source mixed field semi-in-lens design is predicted to have a probe diameter of around half the probe diameter of a SE source magnetic semi-in-lens column design, a factor of improvement which becomes better with increasing probe current. The predicted probe diameter for the CFE source mixed field semi-in-lens design in the 1–100 pA range lies

Fig. 11 Simulated field distributions of a LVSEM mixed field semi-in-lens objective lens design based upon the one proposed by Beck et al. (1995). (a) Electrode/excitation coil layout. (b) Retarding electric field distribution. (c) Immersion magnetic field distribution.

Fig. 12 Simulated probe diameter/probe current dependence for different types of objective lens designs using a SE source operating at a landing energy of 1 keV. The simulated on-axis parameters are, $f = 15.69$ mm, $C_s = 30.6$ mm, and $C_c = 13.29$ mm for a working distance of 5 mm of the S100 lens design, $f = 1.8$ mm, $C_s = 1.5$ mm, and $C_c = 1.3$ mm for a working distance of 2.5 mm of a magnetic semi-in-lens design, and $f = 4.24$ mm, $C_s = 0.77$ mm, and $C_c = 0.62$ mm for a working distance of 5 mm for a mixed field semi-in-lens design. The SE source is assumed to have a brightness of 10^7 $\text{Acm}^{-2} \text{sr}^{-1}$ and an energy spread of 0.5 eV.

Fig. 13 Simulated probe diameter/current dependence of different LVSEM in-lens designs. The simulated on-axis aberration parameters are $f = 1.8$ mm, $C_s = 1.5$ mm, $C_c = 1.3$ mm for a working distance of 2.5 mm for a magnetic semi-in-lens design, and $f = 4.24$ mm, $C_s = 0.77$ mm, $C_c = 0.62$ mm for a working distance of 5 mm of a mixed field semi-in-lens design. The SE source is assumed to have a brightness of 10^7 $\text{Acm}^{-2} \text{sr}^{-1}$ and an energy spread of 0.5 eV, and the CFE source is assumed to have a brightness of 10^8 $\text{Acm}^{-2} \text{sr}^{-1}$ and an energy spread of 0.3 eV.

Fig. 14 Comparison of experimental images from different SEM designs taken at a landing energy of 1 keV of a tin balls-on-carbon calibration specimen. The diameter of the tin balls ranges from a few nanometers to around 60 nm. (a) Image from a conventional thermionic tungsten hairpin source below-the-lens SEM design operating at a working distance of 3 mm. The image magnification is 10,000 and was obtained from a dual beam FEI Quanta 200 3D FIB-SEM. (b) Image from a Schottky electron source magnetic semi-in lens SEM operating at a working distance of 3.08 mm. The image was obtained from a Tescan Gaia3 FIB-SEM. (c) Image from a cold field emission electron source magnetic semi-in-lens SEM operating at a working distance of 2.5 mm and image magnification of 220,000. The image was obtained from a Hitachi Regulus 8230 SEM. (d) A cold field emission electron source semi-in-lens SEM operating in retarding field mode with a working distance of 2.5 mm and image magnification of 200,000. A 3 keV primary beam was used with a -2 kV specimen bias. The image was obtained from a Hitachi Regulus 8230 SEM.

well below 2 nm. In practice, LVSEMs rarely achieve an image resolution of better than 2 nm at a landing energy of 1 keV. This limitation comes mainly from environmental disturbances such as mechanical vibrations and electromagnetic interference, as well as beam-specimen interaction effects.

Fig. 14 shows experimental images from different SEM columns, each having a different electron source/objective lens combination. A calibration specimen consisting of tin balls-on-carbon was used, where the diameter of the tin balls ranged from a few nanometers to around 60 nm. Details about each SEM column design and the operating conditions used are given in the figure caption. These experimental images generally confirm the probe diameter/probe current simulation predictions shown in

Figs. 8, 12, and 13. The tin balls are not visible in the image provided by the conventional thermionic tungsten hairpin source shown in Fig. 14a, which uses a below-the-lens objective lens design. In order to focus this image, broader topographical features on the specimen were used. The next best image resolution is provided by the Schottky source magnetic semi-in-lens column design, shown in Fig. 14b. The bigger size tin balls are visible in this image. A further improvement is obtained by the CFE source magnetic semi-in-lens SEM column image shown in Fig. 14c, in which some of the smaller tin balls become visible. However, the best image, shown in Fig. 14d, is obtained by the CFE magnetic semi-in-lens SEM column operating in retarding field mode (mixed field semi-in-lens). Small nano-size tin balls are clearly visible in this image.

Conclusion

This chapter has summarized SEM basic principles, presented its main figures of merit, and provided an illustration of its high resolution experimental images. The chapter has highlighted instrument developments mainly in the context of low voltage scanning electron microscopy (LVSEM). Looking ahead, there are several other future promising lines of development.

Aberration corrected SEMs might prove useful for some specialized ultra-low voltage/high current applications, but are unlikely to become new general purpose SEMs. This is because SEM image resolution limitations are mainly set by specimen-beam interaction effects, such as the size of the interaction volume and beam induced contamination. These effects already limit the best achievable LVSEM image resolution to lie somewhere between 1 and 2 nm for most bulk specimens, so further reduction of the projected primary electron beam probe size into the sub-nanometer range is unlikely to provide image resolution improvement.

Further work on making cold field-emission (CFE) sources more reliable and easier to use is another promising line of development. Research is presently being carried out on the possibility of using different CFE cathodes, apart from the conventional tungsten one. However, none of them are as yet in a form that can be reliably used in commercial SEMs. Another area of SEM development receiving attention is the challenge of miniaturizing SEM columns, especially for the purpose of making large multi-column LVSEM arrays that can inspect semiconductor wafer specimens. Multi-beam SEM designs have proven to be feasible, where an array of beamlets are created from a single source. However, they have a relatively small overall field of view, typically in the sub-millimeter range, and the optics of each beamlet cannot be individually tuned. The next stage of development will be to make a LVSEM column array that can provide parallel inspection of a large specimen, where each column has its own separate source with individually tunable electron optics.

Another promising area of SEM development is to explore ways of reducing beam induced contamination. Beam induced contamination effects limit both LVSEM ultimate image resolution and image signal-to-noise. Specimen preparation methods borrowed from UHV electron spectroscopy chambers might prove useful, such as pre-cleaning the specimen by low energy ion bombardment or applying UV irradiation.

Finally, there is the possibility of using electron energy spectroscopy techniques inside the SEM. At present, LVSEM lacks a companion material science tool. This is because EDX only functions well for primary beam landing energies of 6 keV or higher, and the landing energies inside LVSEM systems, of 2 keV or less, are not high enough to generate the necessary atomic transitions that emit characteristic X-rays. In principle, energy spectroscopy of SEs and BSEs has the potential for developing new material analysis tools for LVSEM, acquiring material information in a manner similar to Auger electron spectroscopy (AES) or reflection electron energy loss spectroscopy (REELS). The success of this approach will also most likely depend on how effectively beam induced contamination effects can be reduced.

Acknowledgments

The author would like to acknowledge the help of Dr. Zheng Minrui, a Research Fellow at the National University of Singapore, for carrying out the research work to obtain the SEM experimental images presented in this chapter.

Conflict of Interest

The author declares that there is no conflict of interest.

Abstract

Scanning probe microscopy (SPM) is based upon a probing tip, which is scanned across surfaces. The interactions between tip and sample are used to regulate the distance and acquire maps of topography with high lateral resolution. In addition, local information about a variety of physical and chemical properties can be gained. The most common methods of SPM are discussed, including scanning tunneling microscopy (STM) and atomic force microscopy (AFM).

Key points

- Main components of SPM are introduced, including probing tips, piezoelectric scanners, feedbacks, and operation modes
- Introduction to scanning tunneling microscopy (STM) with discussion of tunneling effect and main operation modes
- Atomic force microscopy from noncontact to contact
- Other scanning probe microscopes

Introduction

Scanning probe microscopy (SPM) is a real-space imaging technique, where a needle-type tip is approached and raster scanned across a surface. The microscope can be operated in different environments, such as ambient atmosphere, ultrahigh vacuum, or liquids. In addition, the external variables of temperature or pressure can be adapted to the needs of the experiment. The highest resolution, which was achieved with scanning tunneling microscopy (STM) as well as with atomic force microscopy (AFM), is atomic resolution, where individual atoms can be resolved. Impressive results were achieved with CO-terminated tips by AFM, where submolecular resolution was observed on planar molecules or nanoribbons. In addition to the imaging possibilities, SPM offers additional modes, which can give further insights into the physical or chemical properties of the surfaces. For example, it is possible to determine local mechanical properties, such as elasticity, adhesion, or friction by some adaptations of AFM. SPMs can also be used to characterize electronic properties of surfaces by the use of current vs. voltage curves, which gives information about the local density of states (LDOS). Alternatively, conductive AFM can be used to measure the local conductivity. Kelvin probe force microscopy (KPFM) can give information about the dipolar character of molecules or can determine the local contact potential difference (CPD). If a magnetic tip is used, information about the magnetic structure can be gained.

The chapter will give an overview about the basic components of SPM, which are the probing tip, scanning units, controllers, and vibration isolation. The methods of STM and AFM will be discussed in more detail because these are the most common SPMs. A collection of other SPMs, such as scanning nearfield optical microscopy (SNOM), scanning nearfield acoustic microscopy (SNAM), scanning ion conductance microscopy (SICM), photo-induced force microscopy (PIFM), STM with inverse Photoemission (STMiP), tip Enhanced Raman Scattering (TERS), electrochemical STM (ECSTM), scanning thermal microscopy (SThM), scanning noise microscopy (SNM), scanning potentiometry microscopy (SPotM), scanning capacitance microscopy (SCM), scanning spread-resistance microscopy (SSRM), Tera-Hertz STM (THz STM), or electron spin resonance STM (ESR-STM), will end the chapter.

Principles of SPM

Scanning and Control

All scanning probe microscopes (SPMs) need a scanning unit to move the probing tip across the surface. Tube scanners consist of a piezo-ceramic tube, which has four outer electrodes and one inner electrode. Typically, scan voltages $\pm V_x$ are applied to two outer electrodes and $\pm V_y$ to the other two electrodes. The output of the feedback loop, called z-signal V_z , is applied to the inner electrode. Tube scanners are very compact and have a relatively high resonance frequency. The length extension Δl in z-direction is given by

$$\Delta l = \frac{d_{31} l V_z}{h},$$

where l is the length of the tube, V_z is the voltage applied to the inner electrode, and h is the wall thickness of the tube. The lateral displacement Δx is given by

$$\Delta x = \frac{2\sqrt{2}d_{31}l^2V_x}{\pi D h},$$

where $-V_x$ and $+V_x$ are voltages applied to opposite side electrodes and D is the average diameter of the tube (Chen, 2007; Yang and Huang, 1998). A typical piezo tube with a wall thickness $h = 1$ mm, length $l = 30$ mm, diameter $D = 2.2$ mm, and a transversal piezoelectric constant $d_{31} = 1.8 \text{ \AA/V}$ would give a length extension of $\pm 4.5 \text{ }\mu\text{m}$ and a maximum lateral deflection $\Delta x = \pm 35 \text{ }\mu\text{m}$, when a voltage of ± 250 V is applied. Operation at 4K will result in a reduction of scan range by a factor five.

Piezoelectric tube scanners have a number of deviations from this linear dependence. The most disturbing effect of piezoelectric materials is hysteresis and creep. Forward and backward scan can show significant deviations of the order of 10%. It is most pronounced for the large extensions in the micron range. It is of less importance for high-resolution scans in the nm range.

If hysteresis has to be avoided, a closed-loop scanner can be used, where the position is measured with a capacitive or optical sensor. Closed-loop sensors have high accuracy for metrological applications, but have a limited signal-to-noise ratio, which becomes problematic for high-resolution scans. The mass of closed-loop scanners is usually larger, which also gives some limitations for high speed imaging. The calibration of scanners can be done with suitable calibration structures, which are imaged by STM or AFM mode. Very often, the atomic lattice of surfaces, such as graphite, Au(111), or Si(111) 7×7 , are used for calibration of the scanner. The z-direction is calibrated by imaging of mono atomic steps or microfabricated structures of defined height.

As mentioned before, the z-direction is regulated by a feedback loop (cf. Fig. 1). For STM, the difference between the actual tunneling current and the setpoint current is used to adjust the z-position. This error signal is to be minimized by the controller. In most cases, relatively simple PI controllers are used, where a signal proportional to the error signal (P) and an integrated part (I) is fed to the high voltage amplifier and then to the z-piezo. Values for the proportional gain and integral gain have to be optimized. A simple procedure is to increase the P-gain until oscillations are observed. Then, the P-gain is reduced to 2/3. The integral gain is then increased until first signs of oscillations occur. The gain of the whole feedback loop depends on the tip conditions; thus, it is rather common to optimize the feedback conditions before every experiment. Another concern is the nonlinear dependence of the feedback signal vs. distance. In STM, the logarithm of the tunneling current is an efficient way to linearize across a large distance range. Generally, SPM input signals have a limited range, where a stable operation of the feedback can be achieved. Tip crashes can lead to drastic changes of the feedback characteristics. An automatized tip saver, which retracts the tip at some threshold value, is a valuable tool to minimize tip crashes.

Scanning tunneling microscopy

STM was introduced by Binnig et al. (1982, 1983), where atomic resolution was observed on the surface of Si(111) 7×7 . The microscope is based on the scanning of a probing tip across the surface. A tunneling current of the order of few pA to nA flows

Fig. 1 Scheme of a scanning tunneling microscope. The tunneling tip is mounted to the piezoelectric tube scanner. The tunneling current between tip and sample is used as input signal for the feedback loop. The distance between tip and sample is regulated by keeping the current constant to a preset value. Raster scans in x- and y-directions give an image of the surface.

between the probing tip and the sample. This tunneling current depends exponentially on distance, which gives an excellent input parameter for the feedback loop to control the distance between tip and sample during scanning. Typical separations are of the order of 1 nm, but depend on the exact parameters of bias voltage, set point current, and electronic properties of tip and sample. If the feedback loop is on, lines of constant tunneling current are acquired, which correspond to a height information, sometimes called topography. However, one has to keep in mind that the profiles of constant tunneling current can be affected by local variations of the conductivity of the sample. For example, if several materials are present, the height information can be determined by topography as well as variations of the local electronic structure. The tunneling current is of quantum-mechanical nature, where the wave function decays exponentially across the vacuum barrier. According to Frenkel (1930), the tunneling current, I , is an exponential function of the distance, z , between the metallic electrodes:

$$I(z) = f(V) \exp(-A\sqrt{\Phi}z),$$

where V is the bias voltage, Φ is the work function of the metal, and $A = 1.025 \text{ \AA}^{-1} \text{ eV}^{-1/2}$. With a typical work function of 4.5 eV, one gets an increase of the tunneling current by a factor of 10 by reducing the distance by 1 Å. Therefore, the tunneling current is an extremely sensitive input signal to regulate the distance between tip and sample. Since it needs a current flow, it is mostly limited to metallic or highly doped semiconductor surfaces. Atomic resolution was achieved on a large variety of metallic surfaces, such as Au, Ag, Cu, Pt, Ir, Cr, Ni, or Fe. Suitable preparation under ultrahigh vacuum conditions is needed to image these surfaces. Corrugation heights of some tenths of pm can be observed on closed-packed surfaces. In addition, reconstructions, such as the herringbone reconstruction on Au(111), can be observed (cf. Fig. 2). Highly doped semiconductors can be imaged, of which the most famous example is the Si(111) 7×7 reconstruction. Other examples are GaAs, where gallium and arsenic atoms can be distinguished by application of different voltage polarity (Feenstra et al., 1987).

The ability to measure currents in the sub-pA range widened the applications of STM to thin insulating films, where the current decays partially in the insulating film. On top of these insulating films, organic molecules were deposited and high resolution imaging became possible. It is found that the differential conductance dI/dV curves show peaks at the highest occupied molecular orbital (HOMO) and at the lowest unoccupied molecular orbital (LUMO). If the bias voltage is selected on the HOMO or LUMO peaks, one can image molecular orbitals, which are in excellent agreement with theoretical calculations. Therefore, the deposition of the molecules on insulators decouples the molecules from the metal and gives the opportunity to image undisturbed molecular orbitals. The method works best with planar molecules, such as pentacene, deposited on a few layers of NaCl (Repp et al., 2005).

Atomic force microscopy

AFM is based upon the measurement of the deflection of a cantilever-type spring, which gives the opportunity to measure the force between probing tip and sample (cf. Fig. 3). Typical dimensions of cantilevers are a width of some tens of μm , a length of 100–500 μm and a thickness of 0.1 to 10 μm . This results in spring constants in the range of 0.01–100 N/m. Soft springs with $k_N < 1 \text{ N/m}$ are used for contact force microscopy, where the static deflections are used for force measurements. Harder spring constants $k_N > 10 \text{ N/m}$ are used for noncontact force microscopy or tapping mode AFM, which helps to avoid the jump to contact.

The spring constant of a cantilever with a rectangular cross section is given by

$$k_N = \frac{Ewt^3}{4l^3}, \quad (1)$$

where w is the width, l is the length, t is the thickness of the cantilever, and E is the Young's modulus of the material. The width and length are relatively well-known from the fabrication process or by optical microscopy. Cantilevers can also be characterized by the measurement of the resonance frequency (free cantilever) of the first flexural mode:

$$f_1 = \frac{1.875^2}{l} t \sqrt{\frac{E}{12\rho}}. \quad (2)$$

Fig. 2 (A) STM measurement on Au(111), where the atomic structure is observed with a corrugation of about 10 pm. In addition, the herringbone $22 \times \sqrt{3}$ reconstruction can be observed. Bright areas correspond to dislocation lines, which separate areas of hcp stacking and fcc stacking. (B) Profile of the STM topography along the line as indicated in (A).

Fig. 3 Scheme of an atomic force microscope. The probing tip is attached to the cantilever, where forces between tip and sample lead to deflections of the cantilever-type spring. The distance is regulated with the deflection signal from the cantilever, which corresponds to profiles of constant interaction force.

Table 1 Examples of silicon cantilevers with spring constant and first flexural resonance frequency

Length (μm)	Width (μm)	Thickness (μm)	k_N (N/m)	f_1 (kHz)
125	32	4	44	352
225	38	7	48	190
450	53	2	0.2	13.6

The thickness is most difficult to be determined with reasonable accuracy. Either electron microscopy can be used or the resonance frequency of the first flexural mode, f_1 , is determined, which gives an accurate estimate of the thickness:

$$t = \frac{2\sqrt{12}\pi}{1.875^2} \sqrt{\frac{\rho}{E}} f_1 l^2, \quad (3)$$

where ρ is the mass density ($\rho=2330 \text{ kg/m}^3$ and $E = 1.69 \cdot 10^{11} \text{ N/m}^2$ for silicon).

To give an example, the length of a particular cantilever is $l = 450 \mu\text{m}$ and width is $w = 53 \mu\text{m}$. From manufacturing data, one might expect a thickness of $1 \mu\text{m}$, which would give a theoretical value $f_1 = 6.793 \text{ kHz}$. However, one observes a resonance frequency of 10.3 kHz . Therefore, the corrected thickness is $t = 1.5 \mu\text{m}$ as given by Eq. 3. Accordingly, the spring constant changes from $k_N = 0.02 \text{ N/m}$ to $k_{N,\text{corr}} = 0.09 \text{ N/m}$. Thus, the correction of the thickness is important, at least for soft cantilevers with thicknesses of only a few μm . Further examples are shown in Table 1.

Noncontact atomic force microscopy (nc-AFM): For nc-AFM, the shift of resonance frequency Δf_1 is used to determine the force or force gradient between tip apex and surface. For small amplitudes $A < 1 \text{ \AA}$, the force gradient $\frac{\partial F}{\partial z}$ is given by

$$\frac{\partial F}{\partial z} = -2k_N \frac{\Delta f}{f}. \quad (4)$$

For larger amplitudes, one has to integrate over the oscillation period. An accurate inversion formula is elaborated in the paper by Sader and Jarvis (2004). In this case, the forces can be determined for arbitrary amplitudes A . In the large amplitude case $A > 100 \text{ \AA}$, one observes a dependence of the frequency shift with amplitude, which is proportional to $A^{-3/2}$. Therefore, it makes sense to introduce a reduced frequency shift

$$\gamma_{\text{freq}} = \frac{\Delta f}{f} k_N A^{3/2}, \quad (5)$$

which is useful for comparing results recorded with different experimental parameters (Giessibl and Bielefeldt, 2000). Approximately, one can say that constant γ_{freq} corresponds to constant interaction forces independent of the amplitude A or in the limit of short range forces of constant distance between tip and sample. Actually, it is quite common to calibrate the amplitude by keeping γ_{freq} constant for various amplitudes and to determine the motion of the piezo under the assumption of constant separation between tip apex and sample.

Experimentally, there are a number of possibilities to measure the deflection of the cantilever-type spring. The most common method is the optical beam deflection method, where a laser beam is reflected of the backside of the cantilever (cf. Fig. 4).

Fig. 4 Beam-deflection AFM: A laser beam is used to measure the deflections of the cantilever. The position of the reflected beam on the 4-quadrant photodiode gives information about normal and lateral forces.

The position of the reflected beam is measured with a 4-quadrant photodiode. The difference signal between upper and lower half is proportional to the flexural deflection of the cantilever. The difference between left and right side is related to the torsional deflection of the cantilever, which is then related to lateral forces. Alternative deflection sensors are optical interferometry, where fiber optics is combined with the cantilever. The deflection sensors can be also integrated by a suitable microfabrication process. For example, the piezoresistance of cantilevers can be used as sensor. Other methods involve the measurement of the capacitance or piezoelectricity. At low temperature, tuning forks, as used in quartz watches, are combined with probing tips. The resonance frequency can be measured from the piezoelectric signal. Q-factors of 10,000 to 30,000 were achieved with this setup. A relatively large spring constant of 1800 N/m and resonance frequency in the range of 20 kHz are used (Giessibl, 2003).

An example of nc-AFM imaging of a NaCl(001) surface is shown in Fig. 5, where every other ion is observed. In most cases, the brighter dots correspond to the chlorine ions, but contrast can be reversed by the change of the probing tip. Typical corrugations heights are in the range of 40–50 pm. For controlling the z-distance, the cantilever is excited at its resonance frequency by using a phase locked loop (PLL) or just a frequency demodulator (Fig. 6). By adjusting the excitation voltage also the oscillation amplitude is kept constant. The excitation corresponds to the dissipated energy in one oscillation cycle while the frequency shift is proportional to the conservative forces as discussed above.

Typical force vs. distance curves show an attractive part, which is related to van der Waals forces and electrostatic forces and a repulsive part due to Pauli repulsion forces. In between these regimes, chemical forces due to the interaction between the apex of the probing tip and the sample surface atoms have to be considered (Guggisberg et al., 2000). The earliest examples of atomic

Fig. 5 (A) Constant frequency shift image of NaCl(001) surface. (B) Profile of the topography as indicated in (A). The corrugation is 40–50 pm.

Fig. 6 Scheme of noncontact AFM (nc-AFM).

resolution were acquired on graphite surfaces, where carbon rings were observed. Later, the $\text{Si}(111)7 \times 7$ was observed, where the main contrast was related to the adatom layer, but also rest atoms were resolved under optimum conditions. Atomic resolution on insulators, such as $\text{NaCl}(001)$ is nowadays standard and shows the added value of AFM. A major improvement was to functionalize the probing tip with a CO-molecule, where submolecular resolution was achieved on a number of organic molecules or nanowires (Gross et al., 2009). The main advantage of a CO-terminated tip is its inertness, which gives the opportunity to enter the repulsive force regime. This has demonstrated the highest lateral resolution of chemical structure of molecules. Metallic tips are more reactive and often a bond is formed between tip and sample atoms at close separations, which leads to instabilities and nonreversible surface or tip damage.

In comparison to high-resolution STM, high-resolution AFM is not sensitive to the electronic structure and mostly represents topographic information. Simulation programs assume that the CO molecule senses the ionic repulsion forces, which gives profiles of total charge density. The observed contrast can be affected by the deformations of the CO molecule, which behaves like a small pendulum, which leads to image distortions with some enlargement of intramolecular atom separations (Hapala et al., 2014). Nc-AFM imaging has the highest lateral resolution. In combination with the CO-terminated tips, it has become one of the most efficient ways to observe the structure of molecules on surfaces. It is mostly restricted to planar molecules, but in some cases 3D arrangement was investigated by imaging at different heights (Kawai et al., 2020; Pawlak et al., 2020). An example of the 3,6,14,17-tetrabromodibenzo[a,c]-dibenzo[5,6:7,8]quinoxalino-[2,3-i]-phenazine (TBQP) molecule is shown in Fig. 7, where bromine atoms, visible as bright dots, are still attached to the molecule (Pawlak et al., 2021).

Tapping mode force microscopy: In contrast to noncontact force microscopy, where the frequency shift of the cantilever is measured, tapping mode force microscopy uses the amplitude of oscillation at fixed frequency. Typically, oscillation amplitudes of 2–10 nm are excited close to the resonance frequency. Then the interaction with samples can lead to a shift of the resonance curve, which either increases or decreases the amplitudes. Usually, one assumes that an attractive interaction leads to a decrease of the resonance frequency. Depending on the position of the excitation frequency, the amplitude will be reduced or increased. The amplitude can also be reduced due to an intermittent contact during each cycle, which also motivated the term tapping mode force microscopy.

Fig. 7 (A) The chemical structure of 3,6,14,17-tetrabromodibenzo[a,c]-dibenzo[5,6:7,8]quinoxalino-[2,3-i]-phenazine (TBQP) molecule. (B) Nc-afm imaging of a TBQP molecule with a CO-terminated tip.

Fig. 8 Scheme of the tapping mode AFM.

Thus, the method is not very quantitative, but is a reliable tool to image surfaces. In comparison to contact mode, the lateral forces are reduced. A relatively large amplitude is needed to overcome capillary forces by the restoring force of the cantilever. Tapping mode force microscopy works quite well on biological material with a resolution in the nm range. It was also shown that the tip does not tap the surface (noncontact regime), if relatively small oscillation amplitudes and small changes in the setpoint are selected. The operation in liquids is not trivial, because many oscillation modes of the liquid cell are observed, which are not so easy to distinguish from the resonance frequency of the cantilever. The main criterium is the distance dependence of the cantilever resonance. Alternatively, photothermal excitation of the cantilever can be used, where a modulated laser beam is reflected off the cantilever, heating the cantilever in a periodic manner. The photothermal excitation, which gives a much cleaner spectrum, makes it much easier to find the resonance of the cantilever in liquids (Fig. 8).

Phase imaging: If the cantilever is operated at fixed frequency, one can measure the phase shift between the excitation signal and the cantilever oscillation. Phase images can be acquired on heterogeneous surfaces, which can show strong material contrast. The interpretation of the phase images is not completely clarified. If the oscillation is sinusoidal, one can relate the phase shift to energy dissipation. If the wave-form is distorted due to contact formation, the interpretation is more complex. There are also attempts to relate the phase shift to physical properties, such as elasticity or viscosity, which is to some extent possible for relatively soft materials, where nonlinear effects are not dominant.

Pulsed force mode: The pulsed force mode is a nonresonant intermittent contact mode, where the sample is modulated. The response of the cantilever is acquired with fast data acquisition, where a full force vs. distance curve is visible, including snap to repulsive contact and pull-out of the contact. When the maximum adhesion peak is reached, the cantilever jumps out of contact and free oscillations of the cantilever are visible. Each approach and retraction cycle can be analyzed, where the stiffness of the contact, the maximum normal force, and the maximum adhesive force can be determined. In combination with a suitable elasticity model, it is possible to determine the local elasticity of polymeric samples or biological material. The method works well in liquids and gives some quantitative values about elasticity and adhesion.

High-speed AFM: The scan speed of AFM can be increased by increasing the resonance frequency of the cantilever. Microcantilevers are fabricated, which are reduced in dimensions compared to conventional AFM: A length of 5–10 μm is combined with a width of a few μm . The corresponding resonance frequency is in the range of 1–10 MHz. The mechanical relaxation time

$$\tau = \frac{Q}{\pi f_1} \quad (6)$$

is given by the Q-factor of the cantilever and the resonance frequency of the first flexural mode. With $f_1 = 1$ MHz and $Q = 2$ (typical Q-factor in liquids), one gets 0.6 μs , which allows to operate the feed-back loop in the 100–500 kHz range. The benchmark of high-speed AFM is the number of frames per seconds (fps). Some tens of fps were achieved with microcantilevers and optimized scanners. Examples of imaging of the motion of biomolecules in liquid environment were reported. For example, the motion of an individual myosin protein walking along an actin filament was observed by high-speed AFM (Ando, 2012).

Bimodal AFM: In addition to the oscillation of the first flexural mode, one can also oscillate higher modes, such as the second flexural mode or the first torsional oscillation mode (Kawai et al., 2009, 2010b). In bimodal AFM, the microscope is operated with

constant frequency shift of the first flexural mode and the second flexural mode is oscillated with smaller amplitude. In this case, the second mode is shown to be proportional to the force gradient, whereas the first mode is related to an average of the normal force, as described by the Sader–Jarvis method. Alternatively, the first flexural mode is combined with torsional oscillation mode. It is found that the shift of the torsional resonance frequency gives higher resolution than normal nc-AFM. To first approximation, the torsional signal is related to the lateral force gradient.

Kelvin probe force microscopy (KPFM): It is based on AFM in tapping or noncontact mode, where the applied voltage is varied and electrostatic forces are measured separately (Sadewasser and Glatzel, 2011; Sadewasser and Glatzel, 2018; Glatzel et al., 2022). While in electrostatic force microscopy (EFM), the electrostatic forces are measured qualitatively, in KPFM, a DC bias voltage is applied between tip and sample to compensate the electrostatic forces. KPFM was first developed by Nonnenmacher et al. (1991) and allows to image surface electronic properties, namely, the contact potential difference (CPD). The name “Kelvin probe force microscope” originates from the macroscopic method developed by Lord Kelvin in 1898 using a vibrating parallel plate capacitor arrangement, where a voltage applied to one vibrating plate is controlled such that no current is induced by the vibration (Kelvin, 1898). The reduction of this exact principle to the microscopic scale, however, results in a poor sensitivity, since the size of the capacitor plates is too small to generate a sufficient current. Therefore, in KPFM, the electrostatic force is measured instead and a DC bias voltage corresponding to the CPD is applied to the sample (or the tip) in such a way that the electrostatic forces between tip and sample are minimized. Thus the CPD at atomic and molecular scale also called local CPD (LCPD) can be measured with high spatial and energy sensitivity (Bocquet et al., 2008; Enevoldsen et al., 2008; Kawai et al., 2010a).

The electrostatic force is typically described by a capacitor model with a voltage-independent capacitance, which contains all information on the geometrical details (Hudlet et al., 1998). It quadratically depends on the applied voltage and is measured by force vs. bias voltage curves. The frequency shift signal in nc-AFM follows a parabolic shape depending on the position above the sample and has a maximum exactly at the point where the average electrostatic forces are zero. In many cases this assumption is sufficient and by introducing an AC (V_{AC}) and DC (V_{DC}) voltage component and the CPD (V_{CPD}), the electrostatic force can be described by

$$F_{el} = \frac{1}{2} \frac{\partial C}{\partial z} V^2 = F_0 + F_{\omega} + F_{2\omega}, \quad (7)$$

where

$$F_0 = \frac{\partial C}{\partial z} \left[\frac{1}{2} (V_{DC} - V_{CPD})^2 + \frac{V_{AC}^2}{4} \right], \quad (8)$$

$$F_{\omega} = \frac{\partial C}{\partial z} (V_{DC} - V_{CPD}) V_{AC} \sin(\omega t), \quad (9)$$

$$F_{2\omega} = -\frac{\partial C}{\partial z} \frac{V_{AC}^2}{4} \cos(2\omega t). \quad (10)$$

The 0-component induces a static bending of the cantilever and is similarly as the 2ω -component proportional to the square of the applied AC voltage and the distance dependent capacitance gradient. The ω -component is directly proportional to AC voltage, the capacitance gradient, and the difference between applied DC voltage and CPD. Typically in KPFM setups, this ω -component or its gradient is detected and minimized by applying a DC voltage compensating the CPD and resulting ideally in $F_{\omega} = 0$. A limitation of this description is the fact that not in all cases the capacitance is independent of the applied voltage, especially in the case of semiconducting surfaces (Polak and Wijngaarden, 2016; Glatzel et al., 2022).

Two main modes of detecting and compensating the electrostatic forces separately from the other forces are the amplitude (AM) and frequency (FM) modulated techniques. Both offer not only certain benefits but also drawbacks that have to be taken into account and are described in several publications (Krok et al., 2004; Glatzel et al., 2003), the most recent overview and thorough comparison was given by Axt et al. (2018).

As an example, a measurement of hybrid organic–inorganic lead halide perovskite surface prepared for the application in solar cells is shown in Fig. 9. To avoid contamination and degradation of the film, the sample was prepared, transferred, and analyzed under inert gas N_2 atmosphere. A Flex-AFM system from Nanosurf was used in tapping mode with a nominal amplitude of 3 nm and a feedback setpoint of 80%. The used cantilever was a PtIr-coated cantilever from Nanosensors (PPP-NCLR) with a resonance frequency of $f_1 = 158$ kHz. For KPFM, the AM mode at the second resonance of the cantilever $f_2 = 985$ kHz was applied with an AC bias voltage of 500 mV applied together with the compensation voltage to the sample. The overview image with a size of $4 \times 4 \mu m^2$ shows the polycrystalline character of the surface. The simultaneously measured CPD shows variations of up to 100 mV induced by different facet orientations, chemical composition, and grain boundaries. These variations become more apparent in the magnified measurement below showing clearly the variations between the grains which will finally impact the properties of the resulting solar cell devices. With an appropriate calibration of the work function of the cantilever, absolute work function values can be extracted.

Friction force microscopy (FFM): It is operated in repulsive contact, where the deflections in normal direction (normal force) and the deflections in lateral direction (lateral force) are measured. If the beam deflection method is used to measure the deflections, the torsional signal is directly related to the lateral forces. To convert the deflections into forces, one needs the torsional spring constant, which is given by

Fig. 9 Topography z (A and C) and contact potential difference CPD (B and D) of a perovskite surface measured by tapping mode AFM in a glove box with nitrogen gas and in AM-KPFM mode. C and D are a magnification of the area indicated with a *red box* in A.

$$k_T = \frac{Gwt^3}{3h^2l}, \quad (11)$$

where G is the shear modulus of the cantilever material.

Dissipation force microscopy: In order to keep the oscillation amplitude A constant during nc-AFM operation, one has to apply an excitation voltage A_{exc} to a dither piezo. The free cantilever has some internal damping, which gives the reference value $A_{exc,0}$. If the tip is approached to the surface, one can determine the energy loss per second due to dissipative interactions by equation:

$$P_{tip} = \frac{1}{2} \frac{kA^2\omega}{Q_0} \left(\frac{A_{exc}}{A_{exc,0}} - 1 \right), \quad (12)$$

where k is the spring constant, Q_0 is the Q-factor of the free cantilever, and ω is the resonance frequency in rad/sec. Typical dissipation power is on the order of 10^{-15} W, which can be related to atom reordering on the tip or sample on the time scale of the oscillation period, which then gives dissipation due to hysteresis, where in downward and upward motions of the tip, different atomic structure is encountered. It is also very common to indicate the power loss in energy loss per cycle, which is found to be in the range of meV up to eV per cycle (Yildiz et al., 2019).

Magnetic force microscopy (MFM): In magnetic force microscopy, a ferromagnetic tip is attached to the cantilever, either by evaporation of materials, such as Co, or by glueing a small piece of a ferromagnet, such as cobalt samarium. Then domain walls on ferromagnetic samples can be observed by operation in noncontact mode. The forces due to magnetic interactions are relatively small and the separation between tip and sample has to be kept large in order not to alter the domain structure by the probing tip.

Other SPMs

Other members of the SPM family are described in this section. All SPMs have a probing tip, which can be rather different from the standard metallic tips of STM (cf. Fig. 10).

The *scanning nearfield optical microscopy (SNOM)* uses a glass fiber, which is coated with a metallic film. Then, light is coupled into the fiber. The evanescent light interacts with nanometer-sized objects on the surface, which changes the far field intensity, which is detected by a suitable detector.

Fig. 10 A collection of scanning probe microscopes as described in the main text.

Scanning nearfield acoustic microscopy (SNAM) excites an acoustic wave with a piezoelectric transducer. Hydrodynamic losses lead to a damping of the SNAM signal when the sensor is approached to the surface.

Scanning ion conductance microscopy (SICM) uses a micropipette immersed in an electrolyte and measures the ion current. If approached to the surface, the cross-section of ion path is reduced and the conductance is reduced (Lipson and Hersam, 2013).

Photo-induced force microscopy (PIFM): Light illumination of the probing tip in close proximity to the samples leads to photo-induced polarizability. If modulated at the resonance of a cantilever, one can detect photoinduced forces. The change of the wavelength gives information about the absorption characteristics of the material, which is a way to identify components of heterogeneous surfaces.

STM with inverse Photoemission (STMiP) or scanning tunneling induced luminescence microscopy (STIM): Injection of electrons into metallic films leads to the emission of surface plasmons. If molecules are decoupled from the metallic substrate by a thin insulating film, it becomes possible to inject electrons into the molecules and to observe electroluminescence. Apart from the luminescence line, one can also observe vibrational modes, where the spectrum is in good agreement with Raman spectra (Doppagne et al., 2017).

Tip-Enhanced Raman Scattering (TERS): The metallic tip apex in vicinity to a metallic substrate gives a strong enhancement of the electromagnetic field. By matching the resonance of the nanocavity plasmon to molecular vibrations, it becomes possible to increase the Raman sensitivity. Single porphyrin molecules can be imaged with submolecular resolution. Molecular vibrations are suitable to get a fingerprint to identify subgroups of a molecule (Zhang et al., 2013).

Electrochemical STM (ECSTM) and scanning electrochemical microscopy (SECM): The probing tip is immersed in an electrolyte. By suitable isolation, the ionic current can be reduced and the tunneling current is measurable (ECSTM) (Wittstock et al., 2007) or it is directly detected and electroactive ions or molecules in the solution are imaged with spatial resolution (SECM) (Sun et al., 2007; Martin et al., 2014). The sample can be modified in the electrochemical cell.

Scanning thermal microscopy (SThM) uses a miniaturized thermal sensor at the apex of the probing tip. Local temperature inhomogeneities due to heat sources, such as electrical currents in wires, can be observed. If heated periodically, one can get information about the thermal conductivity as well as the thermal diffusivity. If a wire is heated periodically with a frequency f , one can get information about the Joule heating as well as the Peltier component by the measurement of f and $2f$ components (Menges et al., 2016).

Scanning noise microscopy (SNM) measures the mean square noise current in an STM. It can be shown that this is Johnson noise, which depends on temperature. If the tip is heated, a thermovoltage builds up, which then can be used to map different materials on the surface. It is also found that the current noise doubles from single- to double-charge transfer in a junction between superconductive tip and superconductive sample (Bastiaans et al., 2019).

Scanning potentiometry microscopy (SPotM): A voltage is applied across the sample, which can be used to investigate the electrical potential landscape of wires or assemblies of nanoparticles. Defects in nanowires or percolation paths in nanoparticle assemblies can be observed by this method.

Scanning capacitance microscopy (SCM) measures the capacitance between the tip and sample. If stray capacitances are sufficiently reduced, the method is very well suited for the characterization of semiconductor surfaces, where the depletion layer leads to a reduction of the capacitance. Maps of dopant concentrations can be deduced from these measurements (Williams, 1999).

Scanning spreading resistance microscopy (SSRM) measures the current between a conductive cantilever and a semiconductive surface. The current is limited by the spreading resistance, which can be related to dopant concentration of the sample. Therefore, maps of dopant concentrations can be recorded, if the sensor is calibrated with a suitable sample, where defined impurity concentrations are observed (Eyben et al., 2002).

THz STM uses a THz laser pulse in combination with STM, where the THz pulse adds an additional electrical field to the junction, which can open the current flow through molecular orbitals, such as LUMO or HOMO. Time resolution in the sub-ps becomes possible, which gives the opportunity to observe ultrafast dynamics of molecules (Cocker et al., 2013).

Electron spin resonance STM (ESR-STM) is a combination of an RF-field and spin polarized STM, where the magnetoresistance is measured at the electron spin resonance (Baumann et al., 2015). At different static B-fields, the resonance condition is related to the Zeeman energy splitting. Small z-excursions of the magnetic adsorbate atom in the inhomogeneous field of the magnetic tip lead to the B_1 variation, which is necessary to induce electron spin resonance.

Conclusion

SPM is a versatile type of microscopy, which can be operated in almost any environment from liquids to vapors or vacuum. STM is an excellent microscope for atomic resolution in combination with LDOS mapping. AFM is widely used for imaging on the nanometer scale in combination with mechanical properties, such as elasticity, adhesion, or friction or electrical properties, for example, work function, capacitance, or local conductivity. The option of nc-AFM imaging with CO-terminated tips gives submolecular resolution of planar molecules. In terms of resolution, SPM has reached the atomic scale with STM and nc-AFM. In addition, many physical and chemical properties can be characterized on the nanometer scale. To determine the chemical composition on the nanometer scale seems still a goal for the future. Techniques like NMR, photoemission, or mass spectroscopy are not easy to be combined with SPM.

Abstract

The basic principles of operation of the two complementary modes of transmission electron microscopy, fixed beam and scanning, are described and related through the reciprocity principle. The nature of image contrast in both is described, both coherent and incoherent imaging modes, and their resolution limits, highlighting recent advances in the correction of lens aberrations. Finally, recent developments including so-called four-dimensional imaging using pixelated detectors and the new imaging modes they make possible are introduced.

Key points

- Image formation in Transmission Electron Microscopy (TEM) and Scanning Transmission Electron Microscopy (STEM); reciprocity.
- Resolution and contrast, contrast transfer function.
- Coherent and incoherent imaging.
- Phase contrast and Z-contrast.
- Future directions.

Introduction

The distinguishing feature of transmission electron microscopy (TEM) is its ability to form images of atomic arrangements at localized regions within materials. It provides a view of the microstructure, that is, the variations in structure from one region to another, and the interfaces between them. TEM plays a critical role whenever macroscopic properties are controlled or influenced by defects or interfaces, for example, in the development of advanced structural materials with their complex microstructure of second phases, or electronic materials, which rely on the exquisite control of interfaces and multilayers. X-ray or neutron diffraction can determine the average structure of complex materials very precisely, but in a material comprised of an intimate array of different phases the average structure may be irrelevant. As condensed matter physics moves toward the study of ever more complex materials, and at the same time interest in nanoscale physics, two-dimensional materials and devices is increasing, TEM or its scanning counterpart STEM, is finding a rapidly increasing role in basic condensed matter physics research.

The unique role of the TEM arises because electrons are charged particles, and therefore, unlike X-rays or neutrons, are able to be accelerated and focused into atomic dimensions by electromagnetic fields. The scattered beams can be collected by a lens and refocused to form a true real space image in the manner of an optical microscope, where each point in the image corresponds to a specific point in the object. Electrons also interact much more strongly with matter and electron diffraction can be performed on materials of nanometer lateral dimensions (Hawkes and Spence, 2019; van Tendeloo et al., 2012). For accelerating voltages of 100–1000 kV, the electron wavelength ranges from 0.004–0.001 nm, orders of magnitude lower than atomic spacings in materials. It would therefore appear relatively trivial to form atomic resolution images of materials. However, it is only very recently that atomic resolution imaging could be said to be at all trivial. The major limitation was realized early in the history of the microscope to be the high inherent aberrations of a round magnetic lens. Until recently, spherical aberration has been the dominant aberration, which leads to a ray deviation of $C_s\alpha^3$, where α is the semiangle of the objective lens. With electron lenses, C_s is of the same order as the focal length. This has meant that only very small apertures could be used, and since microscope resolution is given by $0.61\lambda/\sin\alpha$, where λ is wavelength, the best resolution would be limited by diffraction to $\sim 50\lambda$.

It took roughly 50 years from the development of the first transmission electron microscopes in the 1930s to achieve sufficient electrical and mechanical stability to allow imaging of crystal lattices at 0.2–0.3 nm resolution in the 1980s. Over the next 20 years, resolution improved incrementally to 0.1–0.2 nm. In the last 20 years or so it has finally proved successful to compensate for the dominant lens aberrations using a series of non-round magnetic lenses, thanks to the development of solid-state devices, specifically the computer, and charge-coupled-device (CCD) detectors. The gain in resolution over the last few years is comparable to that seen in the previous few decades. Sub-Ångstrom resolution has indeed become almost trivial, and materials are revealing their atomic-scale secrets like never before. The pace of materials physics has hugely increased as a result.

Aberration-correction brings more than just resolution; better resolution brings increased sensitivity, and the imaging of single atoms within materials and on their surfaces, together with their spectroscopic identification by electron energy loss spectroscopy (EELS) is also practically routine. Furthermore, entirely new modes of microscopy have appeared. Most promising is the development of so-called 4D STEM, where the probe still rasters a 2D region of specimen, but the detectors are replaced by a pixelated detector to record the entire 2D diffraction pattern at each probe position, a 4D data set. This allows the detector configurations to be determined after the scan, which can then be analyzed in multiple ways to produce complementary image modes and even map electric and magnetic fields at the atomic scale.

Electron optics of the microscope: STEM vs. TEM, reciprocity

Fig. 1(a) shows a schematic ray diagram for conventional TEM (Williams and Carter, 2009; Carter and Williams, 2016). The specimen is illuminated through a condenser aperture, and transmitted electrons are gathered by the objective lens and recombined into an image. Historically, the size of the condenser aperture was always been chosen to be as small as practically possible to provide a close approximation to parallel illumination. Such is required for diffraction contrast imaging, when only one diffracted beam is passed through the objective aperture. With parallel illumination crystal defects such as dislocations, precipitates and interfaces are observable, and many details of their atomic structure can be obtained indirectly by detailed analysis of image contrast (for example, lattice shifts across an interface, the intrinsic or extrinsic nature of stacking faults, coherency strains of precipitates, Burgers vectors of dislocations). Nearly parallel illumination provides a long coherence length in the specimen, approximately λ/β , where β is the illumination semiangle. For small β many lattice spacings are illuminated in phase, an example of coherent imaging. If the objective aperture α is opened up to include several diffracted beams, the conventional TEM lattice-imaging mode is obtained, often known as high-resolution electron microscopy (HREM), another example of coherent imaging.

In scanning transmission electron microscopy (STEM) the electron beam is focused to a small probe and scanned across the specimen (Pennycook and Nellist, 2011). Fig. 1(b) shows the ray diagram; detectors are used to pick up a signal which is used to form an image pixel by pixel as the probe is scanned. The STEM allows complete flexibility in choice of detector, and multiple detectors are normally used giving complementary information. For example, an annular dark field (ADF) detector collects electrons scattered out of the beam and gives an image of mass thickness, that is, a signal that increases with increasing scattering cross section and specimen thickness; a hole appears dark. A bright field (BF) signal can also be detected using an on-axis detector (holes appear

Fig. 1 Ray diagrams for (a) the TEM and (b) the STEM, showing the reciprocal nature of the optical pathways. The TEM image is obtained in parallel, the STEM image pixel by pixel by scanning the probe. The STEM also provides simultaneous annular dark field (ADF) imaging. Actual microscopes have several additional lenses and the beam limiting aperture positions may differ.

bright). If the bright field detector subtends a small angle β at the specimen, then it is clear from comparing the two ray diagrams in Fig. 1 that the only difference in the optics of the two forms of microscope is the direction of the electron beam. The major source of image contrast is elastic scattering, for which only the scattering angle is important—not the direction of propagation (an example of time-reversal symmetry in physics). This is one example of the principle of reciprocity, where interchange of source and detector leads to the same image, and explains why images formed in bright-field STEM may show identical contrast behavior to those in TEM. If the bright field detector aperture is small, these images are coherent images exactly equivalent to bright field TEM images.

Reciprocity applies even if aberration correctors are added to both columns. In TEM the corrector is placed after the specimen to correct the objective lens aberrations, while in STEM it is placed before the specimen, the purpose being again to correct the aberrations of the objective lens (now used as a probe-forming lens). Fig. 1 makes clear that for the same set of aberration parameters and equivalent angles before and after the specimen, the same images are to be expected, and this is seen experimentally. However, reciprocity does not mean the images will have the same signal to noise ratio. Before aberration correction the angle β necessary to ensure good coherent imaging conditions was so small that the STEM image used only a small fraction of the electrons passing through the specimen. This resulted in noisy images and unnecessary specimen irradiation. With aberration correction, not only can the objective aperture α be made much larger, but β can also be increased and STEM bright-field imaging becomes a useful practical possibility.

The primary motivation for the STEM has been its ability to detect signals other than the bright field image, in particular, the ADF image. Based on the concept of a coherence width in the specimen, if the angle β is sufficiently large, the coherence width in the specimen is below the typical atomic spacings in materials. Although the third dimension along the beam direction must also be considered, the ADF image does represent a good approximation to incoherent imaging. An incoherent image gives a simple relationship between the object and image, as in a camera, and is easier to interpret than a coherent image which can show contrast reversals (atoms may be light or dark). The very different characteristics of coherent and incoherent imaging will be discussed in the next section.

One of the advantages of STEM is that it allows for microanalysis, with the same probe as used for imaging, using one or more additional signals generated as the beam passes through the specimen. Perhaps the most important of these is inelastic scattering, which allows elemental identification from inner shell excitations. Furthermore, the fine structure at the absorption edges carries information about the electronic structure of the excited atom. EELS is equivalent to X-ray absorption spectroscopy, but is available with the spatial resolution of the probe (Egerton, 2011). In the so-called spectrum-imaging mode, one complete spectrum is recorded for each pixel in the image. Similar information can be obtained on a TEM using an imaging filter, which produces 2D images corresponding to particular energy losses. A set of such images at different energy losses is somewhat equivalent to a spectrum image on the STEM. However, reciprocity does not apply to inelastic scattering and there are important differences between TEM and STEM: in the TEM the inelastically scattered electrons must be focused by the image-forming lens which leads to problems with chromatic aberration, whereas in the STEM there are no imaging lenses after the specimen. Although chromatic aberration correctors have been developed this greatly increases the cost and complexity of a microscope.

Energy Dispersive X-ray Spectroscopy, known as EDX or EDS, collects x-rays emitted as the atom relaxes into its ground state following inner shell excitation, and the x-ray energy is again characteristic of the element. The peak resolution is much lower than for EELS, but the peaks lie on a lower background. The major problem is the low efficiency of collection. X-rays are emitted over 4π steradians and only a small fraction can be collected by the detector, whereas the corresponding core loss electrons are forward peaked and a high fraction can be collected for EELS. Recently, much larger collection angles have become feasible, and even multiple detectors have been used, so that atomic resolution EDX mapping is now feasible. Other possible imaging signals include the secondary electrons for imaging surfaces and visible photons (cathodoluminescence) for mapping optical properties.

As mentioned above, microdiffraction, or more recently nanodiffraction patterns can be recorded with an imaging detector in STEM, a so-called pixelated detector. This is very useful for identifying minority phases within bulk materials or new phases not possible to synthesize in large volumes, and also for quantitative measurements of charge modulation. For long wavelength modulations electron diffraction is much more sensitive than X-ray diffraction because of the cancellation of the scattering due to the electrons and nucleus; electron scattering sees the imbalance of charge, whereas X-ray scattering sees the total electron density and is less sensitive to small changes.

For much of the history of electron microscopy it was not possible to have high-resolution STEM and TEM imaging in a single machine. In recent years however great advances have been made in instrument design, and it is now perfectly feasible to purchase microscopes that will give good performance in both modes of operation, often simply at the push of a button. It is also possible today to purchase an instrument with two aberration-correctors, one before the specimen to correct the probe and one after the specimen to provide parallel-detection phase contrast imaging, although some compromises need to be made. Generally, two machines are preferable to one combined instrument, but at higher cost.

Principles of image formation

Coherent imaging

With parallel illumination, a crystal aligned near a zone axis will generate a set of diffracted beams leaving the sample at specific angles, as depicted in Fig. 2(a). The objective lens brings these beams to a focus in its back focal plane to form the diffraction pattern. In diffraction contrast imaging, one diffracted beam is passed through a small objective aperture and the resulting image represents a

Fig. 2 (a) Ray diagram for coherent phase contrast imaging of a crystal. Diffracted beams emerge from the specimen at specific angles and are brought to a focus in the back focal plane of the objective lens. They are recombined in the image plane. Imaging is therefore two consecutive Fourier transforms. (b) Vector diagram for a weak phase object showing the incident beam, a small scattered beam with $\pi/2$ phase change and the resultant transmitted beam. Lens aberrations are used to rotate the phase of the scattered beam an additional $\pi/2$ to create amplitude contrast from the phase changes. (c) Contrast transfer functions for an uncorrected 300 kV microscope, solid line, ($C_s = 0.6$ mm, $\Delta f = -45$ nm, energy spread 2 nm typical for a Schottky field emission source), a corrected 300 kV microscope, dotted line, ($C_s = -37$ μm , $C_5 = 100$ mm, $\Delta f = 5$ nm, energy spread 1 nm typical for a cold field emission source), and a 200 kV microscope with full correction of all 5th order aberrations, dashed line, ($C_s = 23$ μm , $C_5 = -2$ mm, $C_7 = 100$ mm, energy spread 1 nm). The upper trace is for $\Delta f = 1$ nm giving white atom contrast in a thin specimen, the lower one is for $\Delta f = -2$ nm giving black atoms.

map showing the distribution of diffracted intensity from the specimen. The crystal lattice is unresolved, but the image is useful for studying defects and interfaces. To resolve the crystal lattice itself the objective aperture is opened up to include more than one diffracted beam. Now each point in the image receives contributions from multiple diffracted beams that interfere to generate image contrast, which depends on their relative phases. The principles of coherent phase contrast lattice imaging are best illustrated for the idealized case of a thin sample where multiple scattering can be ignored. The incident electron wave function takes the form of a plane wave Ψ_o , which interacts with the electrostatic potential of the specimen $\phi(\mathbf{r})$ (ignoring magnetic fields). Here, lower case letters refer to three-dimensional variables while upper case variables refer to the two transverse dimensions normal to the direction of beam propagation, z , for example, the position vector $\mathbf{r} = (\mathbf{R}, z)$, and the electron wave vector $\mathbf{k} = (\mathbf{K}, k)$. Assuming an incident beam of unit amplitude, a thin specimen acts as a weak phase grating, refracting the incident beam but not changing its amplitude: the exit face wave function is given by

$$\Psi_e(\mathbf{R}) = \exp\{-i\sigma\phi(\mathbf{R})\} \approx 1 - i\sigma\phi(\mathbf{R})$$

where $\sigma = 2\pi m e \lambda / h^2$ is the interaction constant and $\phi(\mathbf{R}) = \int \phi(\mathbf{r}) dz$ is the projected potential (Reimer, 1997; De Graef, 2009; Kirkland, 2010; Spence, 2013). Phase changes in the exit wave therefore map the projected potential of the specimen. These phase changes can be represented vectorially by generation of a scattered wave $\psi_s(\mathbf{R}) = -i\sigma\phi(\mathbf{R})$ which is oriented at $\pi/2$ to the incident wave, as shown in Fig. 2(b). Entering the objective lens, the diffracted amplitude ψ_d is just the Fourier transform of the exit face wave function

$$\psi_d(\mathbf{K}) = \delta(0) - i\sigma\phi(\mathbf{K})$$

where the delta function at $\mathbf{K} = 0$ is the unscattered beam. For a crystal aligned to a zone axis the diffraction pattern consists of a set of sharp diffracted beams at specific directions ($\mathbf{K}$ vectors). With a pure phase object, none of the individual diffracted beam

intensities show an image. To form an image of ψ_s , the diffracted beams must be passed through the objective lens and interfered with the unscattered beam. As shown in Fig. 2(b), the phase of the scattered beams should ideally be rotated an additional $\pi/2$ to convert the phase changes to perfect amplitude contrast. In this ideal case the image amplitude would become $\psi_i(\mathbf{R}) = 1 \pm \sigma\phi(\mathbf{R})$ and the intensity $I(\mathbf{R}) = \psi_i(\mathbf{R})^2 = 1 \pm 2\sigma\phi(\mathbf{R})$. In practice, the most convenient source of additional phase changes are the lens aberrations themselves, in particular, defocus. The phase change introduced by the objective lens is referred to as the transfer function phase factor $\exp[i\gamma(\mathbf{K})]$ where

$$\gamma(K) = \pi \left(\Delta f \lambda K^2 + \frac{1}{2} C_3 \lambda^3 K^4 + \frac{1}{3} C_5 \lambda^5 K^6 \right)$$

if only the rotationally symmetric aberrations are included so that $K = |\mathbf{K}|$. Here Δf is defocus, C_3 is the third order spherical aberration coefficient, usually referred to simply as C_s before aberration-correction became viable, with typical values of the order of 1 mm. In a microscope corrected for third-order aberrations, the fifth order spherical aberration coefficient C_5 takes over as the limiting aberration. Today, aberrations up to and including fifth order are often corrected. The diffraction amplitude transmitted by the lens becomes

$$\psi_d(\mathbf{K}) = \delta(0) - i\sigma\phi(\mathbf{K}) \exp[i\gamma(\mathbf{K})],$$

and for small phase changes the intensity becomes

$$I(\mathbf{R}) = 1 - 2\sigma\phi(\mathbf{R}) \otimes f(\sin \gamma(\mathbf{K})).$$

The phase changes $\phi(\mathbf{K})$ contribute to the image with a contrast given by $\sin\gamma(\mathbf{K})$, which is therefore referred to as the phase contrast transfer function, and the image is given by a convolution of the projected potential with the Fourier transform of $\sin\gamma(\mathbf{K})$.

The different aberrations depend on spatial frequencies to different powers and can therefore only be approximately balanced over a finite range. Fig. 2(c) shows examples for some uncorrected and aberration-corrected microscopes. Note phase contrast imaging provides no contrast at zero spatial frequency because there is negligible additional phase change from lens aberrations. An uncorrected microscope shows rapid contrast oscillations at high spatial frequencies where the $C_s K^4$ term increases very rapidly; such oscillations are largely avoided in the corrected microscopes. The substantial drop in contrast at high spatial frequencies is due primarily to the finite energy spread of the beam. In this regard the cold field emission source is preferable to the Schottky thermal source. One characteristic of phase contrast is immediately apparent. The defocus phase factor is used to balance the dominant term in spherical aberration, but changes sign either side of Gaussian focus. In many cases it is possible to reverse the image contrast on changing the focus (see Fig. 2(c)) and atoms may look black or white in a phase contrast image. This can also happen if the specimen becomes thicker and additional relative phase changes occur between the diffracted beams due to dynamical diffraction (multiple scattering). The exit face wave function no longer relates simply to projected potential and becomes increasingly non-local. The general expression for the image intensity is

$$I(\mathbf{R}) = |\psi_e(\mathbf{R}) \otimes P(\mathbf{R})|^2,$$

the square of a convolution of the exit face wave function with the point response function of the objective lens. The point response function is just the Fourier transform of the transfer function phase factor,

$$P(\mathbf{R}) = \int A(\mathbf{K}) e^{2\pi i \mathbf{K} \cdot \mathbf{R}} e^{i\gamma(\mathbf{K})} d\mathbf{K}$$

where $A(\mathbf{K}) = 1$ over the range of the objective aperture. Because the image is given by a square of the convolution, sum and difference spatial frequencies can appear, and for these reasons image simulations are normally required to relate a phase contrast image to an object.

Incoherent imaging

Incoherent imaging provides a simple relationship between the object and image

$$I(\mathbf{R}) = O(\mathbf{R}) \otimes |P(\mathbf{R})|^2,$$

where the object $O(\mathbf{R})$ is simply blurred by the resolution function of the imaging device. Strictly this applies only when each point on the object emits independently of its neighbors so that there are no permanent phase relationships between them and no persistent interference can occur. The coherence length of the sun on earth is about 0.02 mm, so that observation on a larger length scale is effectively incoherent. This is the kind of imaging familiar from the camera, for example, where changing focus merely blurs the image but does not invert the contrast. It also applies to optical microscopy if a large aperture condenser lens is used to give effectively incoherent illumination, as first analyzed by Rayleigh (1896).

In the STEM, $|P(\mathbf{R})|^2$ is the intensity profile of the probe (see Fig. 1(b)). Not every image takes the form of a simple convolution, as seen already for the case of the small axial detector. The requirement for an incoherent image is that all of the scattering (or other generated signal) be collected by the detector. In the case of inelastic scattering or X-ray emission it is relatively simple to collect all of the signal, or at least a representative fraction of it. In the case of elastically scattered electrons it is not so obvious, because collecting

all of the transmitted electrons will give no image contrast; the specimen does not absorb any electrons, it only scatters them, and detection of those scattered electrons is therefore necessary to generate an image.

One way to form an incoherent image is to detect all of the scattering. Then the detected signal is *insensitive* to any interference that may be occurring among different scattered beams. Interference rearranges intensity but the total scattering is constant, by conservation of energy. The annular detector provides a close approximation to incoherent imaging because it can be arranged to average over a large number of diffracted beams. The inner detector angle should also be large to avoid being dominated by a few low order beams around the inner hole. In practice, the image still shows strong incoherent characteristics even if the inner angle is just larger than the objective aperture angle, which is a mode that gives efficient dark field imaging of single atoms and was the original motivation for the introduction of the detector by [Crewe et al. \(1970\)](#).

High angle scattering comes from the sharpest part of the atomic potential, the nucleus, and its intensity is approximately proportional to the square of atomic number (Z). An annular detector with a large hole therefore gives an image showing strong Z -contrast, also referred to as a high-angle annular dark field (HAADF) image. A sufficiently small probe provides an atomic-resolution Z -contrast image in which atomic columns are seen bright (consistent with it being a dark field image) and their relative contrast is dependent on their projected mean square atomic number. The atomic-resolution contrast again comes from the interference of diffracted beams, except that no phase plates are necessary to create the intensity. The total intensity on the detector rises and falls as the probe scans the lattice because of interference between the diffracted beams reaching the detector, as shown in [Fig. 3\(a\)](#). Each beam takes the form of a disc the size of the objective aperture (the incident beam in STEM). Interference occurs wherever the discs overlap and there are two or more different pathways that can interfere. The conditions for optimum defocus are that the entire area of overlap shows the strongest possible interference as the probe scans. This is quite different from the conditions for optimum phase contrast with a (small) bright field detector, and for the example depicted, the bright field detector covers no overlaps and will show no image.

Smaller spacings will give diffraction discs further apart with smaller regions of overlap and lower maximum contrast. The incoherent transfer function is therefore a slowly decreasing function of spatial frequency, and is obtained from the Fourier transform of the image intensity,

Fig. 3 (a) Schematic showing overlapping diffraction discs on the STEM annular detector. The regions of overlap show interference as the probe scans leading to an atomic resolution image. Note for the spacings depicted the bright field detector covers no overlaps and shows no image. (b) Incoherent object transfer functions for an uncorrected 300 kV STEM, solid line, (conditions correspond to those in [Fig. 2](#) except $\Delta f = -34$ nm), a corrected 300 kV STEM, dotted line, (as [Fig. 2](#) except $\Delta f = 2$ nm), a 200 kV STEM with correction up to 5th order, dashed line, (as [Fig. 2](#) except $\Delta f = 0$ nm).

Fig. 4 Comparison of incoherent and coherent imaging of SrTiO_3 in the $\langle 110 \rangle$ projection in a 300 kV aberration-corrected STEM (a VG Microscopes HB603U with Nion aberration corrector, conditions as in Figs. 2 and 3). A defocus series was taken using ADF and coherent BF detectors simultaneously. (a) the ADF image shows good Z-contrast, with O barely visible, while the phase contrast BF image shows the O columns with high contrast. (b) a through focal series with 4 nm defocus steps from the position of optimum ADF defocus showing how the incoherent ADF image contrast slowly blurs while the phase contrast image shows many different forms of contrast. Images are raw data and show some instabilities. Courtesy of M. F. Chisholm, A. R. Lupini and A. Borisevich.

$$I(K) = O(K) \cdot |P(K)|^2.$$

The transfer function is just the Fourier transform of the probe intensity, and is referred to as a modulation transfer function or object transfer function $|P(K)|^2$. Generally this remains a positive function even as defocus is varied so inverted contrast is not observed. Fig. 3(b) shows incoherent transfer functions corresponding to the coherent contrast transfer functions of Fig. 2(c).

Fig. 4 compares aberration-corrected coherent and incoherent images of SrTiO_3 in the $\langle 110 \rangle$ projection, obtained simultaneously in an aberration-corrected STEM. There is one optimum focus for the Z-contrast image, where the Sr column is brightest and the TiO column less bright. A small peak is present at the oxygen column position but is difficult to detect above the noise because of its low Z. In the phase contrast image, a good image of the oxygen columns is obtained at a defocus of +6 nm, but other images are seen at other defocus values.

The TEM as a nano-laboratory

The TEM is a very versatile instrument and is more like a nano-laboratory than an optical instrument, with a large array of imaging and spectroscopic methods available to probe materials at the atomic scale. Imaging modes are available for electric and magnetic fields (4D STEM, Lorentz imaging, Foucault imaging, holography, Ophus, 2019), and movies have been taken of flux line motion in superconductors. Many applications desire measurements under conditions other than the high vacuum, room temperature environment that is standard for TEM; phase transformations can be observed with a heating holder; studies of catalysis benefit from imaging in an active gas environment; many condensed matter physics investigations require low temperatures; nanowires can be observed while being stretched with simultaneous measurement of conductance. *In-situ* and *operando* microscopy also benefit from aberration correction because it is possible to maintain resolution with a larger gap between the objective lens pole pieces, allowing more room for liquid/gas cells (Ross, 2016) and other devices such as a cathodoluminescence detection system.

Future directions

The achievement of aberration-correction in TEM is likely to be seen as one of the most significant events in the history of the microscope. Aberration-correction substantially improves vision at the atomic scale, through better resolution and better contrast, for the first time giving useful sensitivity to single atoms within materials and on their surfaces. Equal improvements apply to

Fig. 5 Comparison of various modes available with 4D STEM, using a low electron dose. From left to right, ADF, BF, iCOM and ptychography. Courtesy C. Gao, C. Hofer and T. J. Pennycook.

spectroscopy. These developments have brought a new level of insight into the physics of interfaces, defects and nanostructures, issues relevant to the majority of materials and devices of a technological world.

A TEM image presents a two-dimensional projection of a 3D specimen. Stereo techniques have been used to obtain information on the third dimension, and recently, full 3D tomography has been demonstrated at atomic resolution from a series of images taken over a range of sample tilts. 4D STEM is allowing multiple image modes to be obtained from a single data set including HAADF, annular bright and dark field (ABF and ADF), ptychography, differential phase contrast (DPC), integrated DPC (iDPC) and integrated center of mass (iCoM) imaging (Lazić et al., 2016). Such modes not only allow electric fields and charge densities to be quantitatively extracted, they are significantly more efficient than conventional ADF or BF, allowing images to be formed at lower doses. Fig. 5 shows an image of SrTiO₃ taken at a low dose where the ADF and BF images are showing reduced resolution due to the high noise, while the ptychography and iCOM images still retain excellent quality.

Conclusion

The basic imaging modes of the fixed beam TEM and the STEM have been described in relation to each other, the former providing a coherent phase contrast image and the latter both a coherent and also an incoherent image, depending on the geometry of the detector used. Simultaneous coherent and incoherent images are available in STEM, and with a pixelated detector the geometry can be selected after recording the 4D data set, giving huge flexibility. Most 4D pixelated detectors are presently rather slow, but this is a rapidly evolving area and great progress can be anticipated. The STEM also allows simultaneous imaging and analysis through EELS and EDX. *In-situ* or *operando* imaging is usually more efficient in the fixed beam TEM, but the additional imaging and analysis modes available in STEM can be advantageous. The major advances in atomic scale imaging and analysis due to aberration correction are having a significant impact on the fundamental, atomic-scale understanding of materials properties, and synergistic development of new materials through a combination of synthesis/processing, transmission electron microscopy and theoretical calculations is an increasingly productive pathway.

Abstract

Over the past decade, the developments of electron ptychography have revolutionized electron microscopy in the characterization of the atomic structure of matter. Ptychography is a computational imaging technique that has no limits imposed by lens aberrations, thereby offering a spatial resolution well beyond the traditional numerical-aperture-limited resolution with the added benefit of quantitatively accessing and solving the phase of the electron waves. In this review, we summarize the most commonly used ptychographic algorithms and optical configurations, and highlight the recent applications and latest advanced developments. We further discuss the future of multidimensional electron ptychography in combination with other microscopic capabilities, heralding a new era in the characterization of engineered and biological materials.

Key points

- An introduction of electron ptychography and its history (Section “Introduction”);
- An overview of associated algorithms (Section “Ptychography algorithms”) and optical configurations (Section “Optical configuration”);
- The latest applications (Section “Recent applications”) and technological advancements (Section “Recent advances in technical development”) based on newly developed ultra-fast detectors;
- The challenges and future perspectives (Section “Conclusion: Multidimensional ptychography”).

Introduction

To understand how detailed structures at the scale of one billionth of a meter can control the macroscopic properties of condensed matter such as semiconductors, complex oxides (Muller et al., 2008), metals, and biological samples, scientists use transmission electron microscopes (TEMs), which are best known for their ability to form images at the highest resolution of any instrument. Currently, the state-of-the-art aberration-corrected TEM and scanning TEM (STEM) (Muller et al., 2008; Jia et al., 2008; Batson et al., 2002) can produce images with a resolution ranging from a few angstroms (10^{-10} m) to sub-angstrom.

For short-wavelength microscopes, especially electron microscopes, high-quality lenses are difficult to manufacture. Historically, diffraction, and spherical and chromatic aberration limit the resolution of the TEM to approximately $d = 100\lambda$. The conventional magnetic lenses are approximately 200 times poorer than optical lenses in a light microscope—roughly equivalent to viewing an object through the bottom of a beer glass (Hetherington, 2004). The breakthrough in resolution came with a change in hardware, that is, the use of nonround lenses, the principle of which was outlined by Scherzer in the mid-1930s (Scherzer, 1936). This advance was then followed by the presentation of a feasible design by Rose in 1990 (Rose, 1990) and the rapid development of electron-optical hardware components and experimental demonstrations by Haider, Urban, and Krivanek in the late 1990s (Haider et al., 1995; Zach and Haider, 1995; Krivanek et al., 1997, 1999). Now, the experimental resolution limit relative to wavelength has been reduced to approximately $d = 20\lambda$ (i.e., the resolution is 50 pm with a wavelength of 2 pm at an accelerating voltage of 300 kV).

Despite this tremendous progress in resolution, for imaging beam-sensitive weak-phase biological specimens and electric and magnetic fields, which are pure phase objects, only poor phase contrast can be achieved in conventional electron microscopy. As the electron wave passes through a sample, the electron scatters, producing an exit wavefront that is rich in information. Using the wave nature of electrons, a wide range of solid properties, from electric and magnetic field strengths to specimen thickness, strain maps and mean inner potentials, can be extrapolated from the electron's phase and mapped at the nanoscale, or even at the atomic level. Therefore, accurate sensitive imaging of the electron phase signal at high resolution is a long-term goal that engineers continue to pursue in the field of electron microscopy.

Electron holography, the principle of which is based on the wave nature of electrons, was originally proposed by Gabor in 1948 to overcome the deleterious effect of lens aberration (Gabor, 1948, 1949, 1951). Electron holography forms interference patterns (hologram) by the superposition of an electron wave passing through a sample with a reference electron wave; then, from the recorded hologram, an image wave (including amplitude and phase information) can be reconstructed. Because this phase recovery method is completely based on the coherence and interference of the wave, it requires high coherence of the electron beam and a stable reference beam to perform the holographic measurements. A review of the technical details can be found in Lichte and Lehmann (2007).

Ptychography is an alternative phase retrieval technique based on scanning coherent diffractive imaging, as originally proposed by Hoppe (1969), to obtain a direct (noniterative) solution of a crystallographic phase problem. Later, Rodenburg proposed combining ptychography with iterative algorithms to solve this problem, especially for extended noncrystalline samples (Rodenburg et al., 2007). Ptychography records a series of diffraction patterns (constituting a 4D-STEM dataset) as a function of the illumination position, and recovers the sample exit plane wave function using computational algorithms, as shown in Fig. 1C–F. Unlike holography, ptychography does not require a reference beam in the optical configuration, as the diffraction pattern of the field emerging from the object itself acts as an interferometer. Ptychography is considered a lens-less imaging method, which means that it can obtain images without the usage of good quality lenses (such as aberration correctors) and thus, the resolution when using this method is ultimately determined by the diffraction limit.

Fig. 1 Experimental setups of (A) conventional STEM mode and (B) ptychography. (c–f) Workflow of ptychography.

The key advantage of ptychography is the capability of reconstructing the entire wavefield (including amplitude and phase) scattered by an object that is considered to be lost in the context of other imaging methods, such as incoherent STEM imaging. Unlike defocused phase contrast TEM, ptychography is a post-acquisition imaging process, where the image is reconstructed *in silico*. Therefore, the algorithms control the resulting information transfer. The algorithms can be based on either direct methods (e.g., SSB, Rodenburg et al., 1993) or iterative methods (e.g., ePIE, Maiden and Rodenburg, 2009). Furthermore, the resulting image is free from the aberrations of the probe-forming optics, which is not the case for other scanning-type phase microscopies, such as differential phase contrast (DPC) imaging (Rose, 1976).

The recent rise of the popularity of ptychography is due to the new generation of direct electron detectors (Tate et al., 2016; Ballabriga et al., 2013; Ryll et al., 2016), as ptychography requires electron detectors that have readout speeds comparable to the STEM scanning rate (μs to ms timescales for each pixel) and a large dynamic range to record the complete distribution of transmitted electrons, including the low-intensity signals at high angles. In principle, almost every forward scattered electron that has interacted with the object can be counted. With fast electron detectors, ptychography offers the most efficient phase recovery and robustness under low electron dose conditions (Yang et al., 2016a; Pennycook et al., 2019; Pelz et al., 2017) in comparison to other conventional imaging modes (e.g., HAADF, ABF, DPC, and TEM) both in STEM (Yang et al., 2015) and TEM (Pennycook et al., 2019), which leads to significant potential for its application in beam-sensitive samples in the physical (dos Reis et al., 2018) and biological sciences (Pelz et al., 2017; Zhou et al., 2020).

A number of scholarly reviews provide details of the history and theories of ptychography (Rodenburg and Maiden, 2019; Rodenburg, 2008). In light of the current developments of ptychography within the past decade, our intention in this chapter is to provide a brief overview of the associated algorithms (Section “Ptychography algorithms”) and optical configurations (Section “Optical configuration”), to draw attention to the latest applications (Section “Recent applications”) and technological advancements (Section “Recent advances in technical development”) based on ultra-fast detectors and to identify challenges and future perspectives (Section “Conclusion: Multidimensional ptychography”).

Ptychography algorithms

Typical ptychography is based on scanning diffractive imaging, which is compatible with STEM mode, as shown in Figs. 1B and 2 with relevant notation. A convergent electron probe called the probe function, $a(\vec{R})$, is formed at the object plane with an aperture $A(\vec{K})$. After passing through the object, $o(\vec{R})$, the wave function at the exit plane, called the exit wave, $\psi_{\text{exit}}(\vec{R}, \vec{R}_p)$, can be expressed by the product of the probe function and the object transmission function as

Fig. 2 Schematic illustration of ptychography in a STEM configuration and some of the notations used in the following equations. $\vec{K}$ and $\vec{R}$ represent coordinates in real space and Fourier space, respectively.

$$\psi_{\text{exit}}(\vec{R}, \vec{R}_p) = a(\vec{R} - \vec{R}_p) o(\vec{R}) \quad (1)$$

where $\vec{R}_p$ refers to the probe position and $\vec{R}$ represents coordinates in real space.

Then, the exit wave, $\psi_{\text{exit}}(\vec{R}, \vec{R}_p)$, propagates to the far-field plane and is recorded by the detector as a two-dimensional (2D) diffraction pattern for the position $\vec{R}_p$,

$$I(\vec{K}, \vec{R}_p) = |\Psi(\vec{K}, \vec{R}_p)|^2 = |FT_R(\psi_{\text{exit}}(\vec{R}, \vec{R}_p))|^2 \quad (2)$$

As the probe is scanned on the object in a 2D array, at each probe position, a 2D diffraction pattern is recorded; thus, $I(\vec{K}, \vec{R}_p)$ is generated as a 4D data cube, the so-called 4D STEM dataset, which can be further analyzed and used to reconstruct the object transmission and probe functions using either direct methods or iterative methods, as described below.

Direct methods

Single side band (SSB)

Rodenburg first proposed the SSB method (Rodenburg et al., 1993), where the specimen is treated using the weak phase object approximation (WPOA). Hence, the object transmission function can be written as (Rodenburg et al., 1993)

$$o(\vec{R}) = 1 - io_s(\vec{R}), |o_s(\vec{R})| \ll 1 \quad (3)$$

where $o_s(\vec{R})$ is real, is much smaller than unity, and is proportional to the projected atomic potential. By performing a Fourier transform of $I(\vec{K}, \vec{R}_p)$ with respect to probe positions $\vec{R}_p$, under the WPOA, $G(\vec{K}, \vec{Q}_p)$ can be expressed as (Pennycook et al., 2015)

$$\begin{aligned} G(\vec{K}, \vec{Q}_p) &= |A(\vec{K})|^2 \delta(\vec{Q}_p) + A(\vec{K}) A^*(\vec{K} + \vec{Q}_p) O_s^*(-\vec{Q}_p) \\ &\quad + A(\vec{K} - \vec{Q}_p) A^*(\vec{K}) O_s(\vec{Q}_p) \\ &= |A(\vec{K})|^2 \delta(\vec{Q}_p) + O_s(\vec{Q}_p) (A(\vec{K} - \vec{Q}_p) A^*(\vec{K}) - A(\vec{K}) A^*(\vec{K} + \vec{Q}_p)) \end{aligned} \quad (4)$$

There are three main terms, $A(\vec{K})$, $A(\vec{K} - \vec{Q}_p)$, and $A(\vec{K} + \vec{Q}_p)$, the last two of which suggest the displacement of the aperture $A(\vec{K})$ in the Fourier space with a shift $\pm \vec{Q}_p$. According to the value of the shift, $G(\vec{K}, \vec{Q}_p)$ contains double-overlap (DO) or triple-overlap (TO) regions, as shown in Fig. 3A (O'Leary et al., 2021). The amplitude and phase of the experimental $G(\vec{K}, \vec{Q}_p)$ from bilayer graphene in Fig. 3B show the interference at disk overlaps, which contains both the phase information of the specimen and the phase information due to aberrations in the probe forming lens. For the SSB, the lens is assumed to be aberration-free so that the object function, $o_s(\vec{R}_p)$, can be simply retrieved by the following steps. First, the amplitude and phase in one of the double overlap regions in $G(\vec{K}, \vec{Q}_p)$ (one side-band) are summed over all $\vec{K}$ for each $\vec{Q}_p$ to obtain $O_s(\vec{Q}_p)$. Second, an inverse Fourier transform of $O_s(\vec{Q}_p)$ with respect to probe positions $\vec{Q}_p$ is performed, allowing the transmission function in real space $o_s(\vec{R}_p)$ to be subsequently obtained.

The SSB algorithm can be used to achieve a resolution approximately twice the “conventional” resolution that can be obtained by using the same optical arrangement (Rodenburg et al., 1993). This algorithm has been adopted to reconstruct monolayer (O'Leary et al., 2021) and bilayer (Pennycook et al., 2015) graphene and aluminosilicate zeolite samples (O'Leary et al., 2020) (as shown in Fig. 4), in which case the contrast of the ptychographic reconstructions and dose efficiency are found to be greater than those of conventional imaging methods (Pennycook et al., 2019). In addition, the contrast transfer function (CTF) of SSB together with the factors that can affect the CTF was studied in Refs. (Yang et al., 2015; O'Leary et al., 2021).

Wigner distribution deconvolution (WDD)

As mentioned above, in SSB, the specimen is treated as a weak phase object, and the probe is assumed to be aberration-free. However, these two assumptions cannot always be satisfied; thus, at this time, it is difficult to achieve gratifying results with SSB. The WDD approach was first introduced in the early 1990s (Chapman, 1996; Rodenburg and Bates, 1992). In contrast to SSB, WDD is a full reconstruction that takes into account the nonlinear terms through a deconvolution approach and does not rely on the WPOA approximation, which allows a broader range of materials to be reconstructed (Yang et al., 2017). In addition, WDD is capable of measuring and correcting residual lens aberrations. $G(\vec{K}, \vec{Q}_p)$ can be written in the form of convolution (Yang et al., 2017)

$$G(\vec{K}, \vec{Q}_p) = A(\vec{K}) A^*(\vec{K} + \vec{Q}_p) \otimes O(\vec{K}) O^*(\vec{K} - \vec{Q}_p) \quad (5)$$

Fig. 3 (A) Schematic illustration of $G(\vec{K}, \vec{Q}_p)$ under the condition of $|\vec{Q}_p| < \alpha$ and $\alpha < |\vec{Q}_p| < 2\alpha$, where DO and TO represent the double and triple overlap regions (O’Leary et al., 2021). (B) The amplitude and phase of $G(\vec{K}, \vec{Q}_p)$ after applying the same process as that used in (A) on experimental 4D-STEM datasets collected from a sample of graphene. There are also “0” and “ $\pm Q_p$ ” disks, as indicated by white circles, and double and triple overlap regions (Pennycook et al., 2015).

where the symbol $\otimes$ denotes convolution. If we carry out an inverse Fourier transform of $G(\vec{K}, \vec{Q}_p)$ with respect to $\vec{K}$, we can obtain

$$\begin{aligned} H(\vec{R}, \vec{Q}_p) &= \text{IFT}_{\vec{K}}(G(\vec{K}, \vec{Q}_p)) \\ &= \chi_a(\vec{R}, -\vec{Q}_p) \cdot \chi_o(\vec{R}, \vec{Q}_p) \end{aligned} \quad (6)$$

where χ is the Wigner distribution function. Next, terms related to the probe-forming aperture function can be separated from the reconstructed results using

$$\chi_o(\vec{R}, \vec{Q}_p) = \chi_a^*(\vec{R}, -\vec{Q}_p) H(\vec{R}, \vec{Q}_p) / \left(|\chi_a(\vec{R}, -\vec{Q}_p)|^2 + \varepsilon \right) \quad (7)$$

By doing so, residual lens aberrations can be corrected. Then, Eq. (8) can be applied to obtain $O(\vec{Q}_p)$ and the inverse Fourier transform can be performed to obtain $O(\vec{R}_p)$

$$O(\vec{Q}_p) = D^*(0, -\vec{Q}_p) / \sqrt{D(0, 0)} \quad (8)$$

where $D(\vec{K}, \vec{Q}_p) = \text{FT}_{\vec{R}}(\chi_o(\vec{R}, \vec{Q}_p)) = O(\vec{K}) O^*(\vec{K} - \vec{Q}_p)$.

Fig. 4 Ptychographic reconstructed phase results of (A) monolayer graphene (O’Leary et al., 2021), (B) bilayer graphene (Pennycook et al., 2015), and (C) ZSM-5 (O’Leary et al., 2020).

Since WDD was proposed, it has been demonstrated that by using a Wigner distribution, the complex value of the specimen function at a resolution dictated by the largest collection angle can be obtained. Because this is much larger than the width of the objective lens transfer function of the microscope, the technique offers a practical means of overcoming the long-standing resolution problem in electron microscopy (Nellist and Rodenburg, 1994; Nellist et al., 1995; Bates and Rodenburg, 1989; Rodenburg and Bates, 1992). WDD has been used to reconstruct phase images of BiFeO_3 (Yang et al., 2017), GaN (Yang et al., 2017), and carbon fullerenes (Yang et al., 2016b) at atomic resolution. In addition, as shown in Fig. 5A and B, compared to the reconstructed phase result of gold nanoparticles using the SSB algorithm, the reconstructed result using the WDD algorithm delivers better contrast and higher quantitative phase values because the WPOA is not suitable for gold nanoparticles (Yang et al., 2017). In addition, WDD is able to measure and correct the residual lens aberrations in the phase image through post-acquisition processing, and thus, a higher resolution image can be achieved (shown in Fig. 5C–F) (Yang et al., 2017, 2016b). WDD has also been used to suppress noise (Lee and Barbastathis, 2016; Li et al., 2014).

Even though WDD no longer relies on the WPOA, it still assumes the exit wave to be the product of the probe function and the object transmission function, which makes WDD not strictly applicable to dynamical electron scattering (Yang et al., 2016b). Dynamical electron scattering effects are discussed in Section “Multiple scattering”. Direct methods tend to be applied in focused probe ptychography (Section “Focused and defocused probe ptychography”), which is compatible with the current STEM optical configuration, whereas a defocused probe configuration (Section “Focused and defocused probe ptychography”) is usually implemented with iterative schemes. The following section introduces iterative algorithms.

Iterative algorithms

In general, iterative algorithms rely on the application of measured constraints in the object plane and the far-field (diffraction) plane of intensity information, and the wave function propagation between these two planes is given by the Fourier transform shown in Fig. 6. The process used to find solutions consists of four steps: (1) forward propagate a complex guess object function with a random phase to the diffraction plane by Fourier transform; (2) perform Fourier constraint by replacing the modulus of the computed diffraction pattern with the measured modulus and retain the calculated phase; (3) backwards propagate to the object plane by inverse Fourier transform; (4) perform object constraint and use the calculated phase as a new estimation for the next iteration. These steps are repeated “iteratively” until convergence is achieved.

Fig. 5 The ptychographic reconstructed phases of Au nanoparticles using (A) SSB and (B) WDD are compared, and the results show that WDD delivers better contrast when the sample no longer satisfies the WPOA. (C) and (E) show the reconstructed phase results of Au nanoparticles using WDD before and after aberration correction. (D) and (F) are the Fourier transform results of (C) and (E), respectively. (C–F) demonstrate that WDD can be used to measure and correct residual aberrations, and thus, a higher resolution can be achieved (Yang et al., 2017).

Fig. 6 Schematic illustration of how iterative algorithm works.

The earliest iterative scheme was proposed by Gerchberg and Saxton (1972) and later developed by Fienup (1982). To solve for the object using a single diffraction pattern, a priori knowledge that the object is sufficiently small and isolated must be applied. Several demonstrations of high-resolution imaging with X-ray or electron optics have been reported (Zuo et al., 2003; Miao et al., 1999), but only for samples containing isolated objects, which limits the wider application of this technique. To overcome this limit, Rodenburg first proposed combining the iterative scheme with ptychography to solve for extended noncrystalline samples in particular (Faulkner and Rodenburg, 2005, 2004; Rodenburg and Faulkner, 2004), called the ptychographic iterative engine (PIE)

(Rodenburg et al., 2007). As shown in Fig. 6, by shifting the probe to different positions with partial overlap between neighboring illuminated areas, a series of diffraction patterns can be collected. The partial overlap (Bunk et al., 2008) largely increases the redundancy (Maiden et al., 2011) of the dataset, thus helping the algorithm to converge.

However, PIE still requires a priori knowledge of the incident illumination or probe function. Due to the high redundancy in ptychographic data, this requirement was eliminated with the difference map (DM) algorithm (Thibault et al., 2008, 2009) and the extended PIE (ePIE) (Maiden and Rodenburg, 2009), where both the object function and the illumination function can be extracted from a ptychographic dataset. Such redundancy has been continuously exploited in recent years. There are a number of required experimental conditions, such as accurate knowledge of the probe scanning position (Maiden et al., 2012b; Zhang et al., 2013), noise-free data (Godard et al., 2012; Thibault and Guizar-Sicairos, 2012), and fully coherent illumination sources (Thibault and Menzel, 2013), and the assumption of thin samples (Godden et al., 2014) can be relaxed in recent advanced algorithms. In Section “Recent advances in technical development”, we discuss certain respects of these advanced technical developments. In this section, we give a brief introduction to the basics of the ePIE and DM algorithms.

Ptychographic iterative engine

The theory of the PIE technique can be found in an earlier work (Rodenburg and Faulkner, 2004). Unlike PIE, ePIE starts with initial guesses of both the probe function and the object function (Maiden and Rodenburg, 2009). The reconstruction steps of ePIE are shown in Fig. 7. The algorithm also follows the conventional iteration framework, which consists of the four steps described above. Two major modifications are introduced in the fourth step: both the probe function and the object function are updated using update functions in Eqs. (9) and (10), respectively; for the next iteration, the probe is moved to the next position in the dataset, and the newly updated object function is used as the initial estimate.

Fig. 7 Flowchart of the ePIE algorithm (Maiden and Rodenburg, 2009).

$$o_{j+1}(\vec{R}) = o_j(\vec{R}) + \alpha \frac{a_j^*(\vec{R} - \vec{R}_p)}{|a_j(\vec{R} - \vec{R}_p)|_{\max}^2} (\psi_{\text{new},j}(\vec{R}) - \psi_{\text{old},j}(\vec{R})) \quad (9)$$

$$a_{j+1}(\vec{R}) = a_j(\vec{R}) + \beta \frac{o_j^*(\vec{R} + \vec{R}_p)}{|o_j(\vec{R} + \vec{R}_p)|_{\max}^2} (\psi_{\text{new},j}(\vec{R}) - \psi_{\text{old},j}(\vec{R})) \quad (10)$$

Because a high degree of redundancy can be introduced into the recorded data due to the use of multiple diffraction patterns, instead of a single pattern, as well as the overlap between adjacent probes, the work by Maiden et al. (2011) demonstrated that when using ePIE, the super-resolution information can be extrapolated beyond the aperture of the detector. An electron microscopy work by Hue et al. (2011) demonstrated that ePIE is a very robust algorithm capable of updating the object and the probe at the same time, is resistant to noise, and is able to reconstruct strong phase objects, as shown in Fig. 8.

Difference map (DM)

The DM algorithm proposed by Elser (2003) is one of the iterative projection algorithms. There are two important concepts in the iterative projection algorithms. One is the constraint sets, which refer to a group of points that satisfies a certain condition. The other is the projection functions, which are used to find a point in the corresponding set that has a minimum distance from the initial point. Iterative projection algorithms aim to solve the phase problem by utilizing projection functions to find a point that exists in two constraint sets simultaneously, as illustrated in Fig. 9. In electron ptychography, one of these two constraint sets is the Fourier Constraint Set (FCS), and the other tends to be the Overlap Constraint Set (OCS).

FCS refers to a set of points whose modulus after Fourier transformation equals the square root of the intensity of the recorded diffraction patterns. The OCS states that each view can be factorized as a probe and an object function, and any view that can be decomposed into the product of a “probe” and an “object” function with a known displacement can be regarded as being in the same OCS. Detailed reconstruction steps of the difference map algorithm can be found in Elser (2003) and Thibault et al. (2009).

One of the advantages of the DM algorithm is its ability to reconstruct the object and probe function simultaneously by utilizing the FCS and the OCS (Thibault et al., 2008, 2009), which can realize a significant improvement in image quality. Fig. 10 shows the

Fig. 8 ePIE-reconstructed phase results of FeNi particle aggregates. (A) TEM bright field image of FeNi particles, with blue circles representing the probe positions when collecting 4D-STEM datasets. The probe's initial guess (B) amplitude and (C) phase. After using the ePIE algorithm, the reconstructed amplitude and phase results of the object and probe are shown in (D–E) and (F–G), respectively (Hue et al., 2011).

Fig. 9 Schematic illustration of how the iterative projection algorithms solve the phase problem. Orange and blue lines represent two different constraint sets. By iteratively utilizing projection functions, which find the closest point in the corresponding constraint set to the initial point, the point that exists in both constraint sets can be found.

simultaneously reconstructed phase results of the object and probe functions in scanning X-ray diffraction microscopy. However, the applications of this algorithm have only been demonstrated with X-rays (Thibault et al., 2008).

Optical configuration

There are three fundamental requirements to perform ptychographic experiments (Li and Maiden, 2018). First, the experiment needs a finite-size illumination area that can be shifted with respect to an object either by scanning the illumination or by translating the object through positional grid. Second, a detector can be placed at any plane downstream of the object, although it is normally located at the Fourier plane. Third, the shifting process itself can facilitate direct methods to a solution of the diffraction phase, whereas for iterative approaches, adjacent illumination positions must be partially overlapped. A sufficient degree of overlap leads to the high redundancy in the dataset, which then allows the reconstruction to converge at a unique phase solution (Bunk et al., 2008; Maiden et al., 2011) and thus relaxes the required experimental conditions of ptychography. This makes the method extremely versatile and diverse in terms of experimental setups. The following section briefly introduces a few mainstream optical configurations based on existing electron microscopes.

Fig. 11 Optical configurations of (A) focused-probe ptychography and (B) defocused-probe ptychography.

Focused and defocused probe ptychography

As shown in Fig. 11, both focused and defocused probe ptychography are compatible with the current STEM optical configurations. Placing an ultra-fast detector in the far-field plane to record diffraction patterns would be sufficient for a current STEM instrument to be able to perform ptychographic experiments.

Using an in-focused probe in the object plane (Fig. 11A), focused ptychography has the advantage of coupling with current aberration-corrected STEM capabilities at the atomic scale, including HAADF imaging to extract Z-contrast images (Yang et al., 2016b) and spectroscopy with characteristic X-rays, secondary electrons, and auger electrons, to analyze the elemental composition of the specimen. However, since a detector must be placed within the optic axis, which blocks electrons from entering electron energy loss spectrometer (EELS), the major tradeoff to using ptychography is the complete loss of any ability to use the inelastic electrons, which contain rich elemental composition and bonding information at atomic resolution (typically constituting one of the main rationales for using aberration-corrected STEM). To overcome this issue, hollow ptychography was proposed by Song et al. (2018), in which a hollow-type detector can be used. As a result, hollow ptychography can be performed with EELS to simultaneously provide a high-efficiency phase together with spectroscopic information in a single experiment and is compatible with many 4D-STEM techniques (Ophus, 2019).

The focused configuration also comes with some limits. Inferred from the procedure of SSB or WDD, the scanning step size that is equal to the pixel size in the reconstructed images must be small enough for atomic resolution imaging. As a result, the data volume for the acquisition of a large field of view can increase dramatically. Second, as the electron beam is focused into a fine spot on the sample, to sufficiently reach a low dose condition (i.e., $500 \text{ e}/\text{\AA}^2$), the beam current must theoretically be reduced to approximately 0.1–0.01 pA, which is not tremendously lower than the typical beam currents (1–50 pA) used in normal STEM operation. This fact results in practical difficulties in locating the sample position and focusing the probe.

In contrast, the defocused setup, as shown in Fig. 11B, allows the size of the illumination on the object to be flexibly adjusted by the defocus value so that the beam current can be distributed to a wide region in a controlled manner while ensuring that the total electron dose is largely reduced. The large illumination region also enables a coarse scanning step size to be used, which can significantly reduce the total number of scanning positions and hence the data volume used in the reconstruction for a wide field of view. Note that when using iterative approaches, the resolution of the reconstruction is not compromised by the use of a large step size because it is determined by the maximum collection angle of the detector (Wang et al., 2017; Jiang et al., 2018).

Therefore, the focused and defocused configurations have their own advantages. The former can obtain simultaneous multi-channel signals from conventional detectors and spectrometers at a high spatial resolution, whereas the latter can facilitate low-dose imaging to reach a dose suitable for beam-sensitive materials such as biological specimens.

Fourier ptychography

In both focused and defocused ptychography, the sample is scanned with a spatially confined electron probe, and the object is shifted relative to the probe with partial overlap between neighboring illuminated areas. Then, the diffraction patterns are recorded

in the far-field plane. Since the object plane is considered to be in real space and the 4D-STEM diffraction datasets are collected in Fourier space, this kind of ptychography can also be referred to as real space ptychography. In reciprocity, the diffraction pattern in Fourier space can be treated as the object while the images in real space are collected as 4D-STEM datasets. Fourier ptychography was also proposed by Hoppe, shortly after his work on ptychography. As its name suggests, Fourier ptychography is the reciprocal analog of real space ptychography since the probe function and the object transmission function are in Fourier space.

Given that a plane wave $e^{i\vec{K}_p \cdot \vec{R}}$ is illuminated on the object, $o(\vec{R})$, an exit wave $\psi_{exit}(\vec{R})$ is formed. According to the WPOA approximation, the exit wave can be defined as

$$\psi_{exit}(\vec{R}) = o(\vec{R}) \cdot e^{i\vec{K}_p \cdot \vec{R}}. \quad (11)$$

The exit wave then continues to propagate to the focal plane, where an aperture is placed. After passing through the aperture, the wavefield $\Psi(\vec{K})$ becomes:

$$\Psi(\vec{K}) = FT_R(\psi_{exit}(\vec{R})) \cdot A(\vec{K}) = O(\vec{K} + \vec{K}_p) \cdot A(\vec{K}). \quad (12)$$

When the wave propagates to the detector plane, the detector records the intensity of the wavefield, which is given as

$$I(\vec{R}) = |FT_K(\Psi(\vec{K}))|^2. \quad (13)$$

There are several differences with this approach, compared to conventional ptychography. First, the probe function and the object transmission function in conventional ptychography become the aperture function and the object's Fourier spectrum in the Fourier domain, respectively. Second, the diffraction patterns are captured in real space, while in conventional ptychography, diffraction patterns are captured in Fourier space. Third, the movement of the electron source, which modifies the vector $\vec{K}_p$ in plane wave $e^{i\vec{K}_p \cdot \vec{R}}$, causes the Fourier spectrum of the object to shift $O(\vec{K} + \vec{K}_p)$; however, in conventional ptychography, the shift of the object relative to the probe is controlled by scanning coils, which change the direction of the scanning probe.

Fourier ptychography can reduce hardware requirements, such as the dynamic range of the detector and coherence of electron guns. Fourier ptychography has already been demonstrated in TEM (Haigh et al., 2009), although it is generally called tilt-series reconstruction and has shown an ability to extend the ultimate resolution of the latest generation of aberration-corrected TEMs by 41% relative to that achievable using conventional axial imaging, as shown in Fig. 12.

There are many other derivatives of ptychography, such as near-field ptychography (Robisch et al., 2015; Stockmar et al., 2013), Bragg ptychography (Hruszkewycz et al., 2012, 2017; Godard et al., 2011; Pfeifer et al., 2006), selected area ptychography (Maiden et al., 2015), and single shot ptychography (Sidorenko and Cohen, 2015). Each has a unique experimental setup and requirements but shares the same underlying principle. As these setups have not yet been widely implemented on electron microscopes, they will not be introduced in detail here.

Recent applications

Since ptychography was first proposed, it has been widely used with X-ray optics, including the study of both engineered (Yu et al., 2015; Wilke et al., 2012) and biological (Lima et al., 2013; Giewekemeyer et al., 2010; Wilke et al., 2015; Hemonnot et al., 2016) materials. In electron microscopy, recent developments in regard to coherent electron guns, computing power and, in particular, ultra-fast detectors have significantly accelerated the application of ptychography techniques. With the advantages that it offers, ptychography has great potential in the following application areas.

First, compared to other phase-retrieval or imaging techniques, ptychography has an important advantage of overcoming the limitations of the coherence envelope (the “information limit”) of electron microscopy. Super-resolution ptychography was first demonstrated by Nellist et al. in 1995 (Nellist et al., 1995) with a resolution of 0.136 nm from crystalline Si (see Fig. 13A and B). The atomic resolutions achieved from various samples, such as boron nitride cones (Putkunz et al., 2012), cerium dioxide nanocrystals (D’Alfonso et al., 2014; Morgan et al., 2013) and lanthanum hexaboride (Wang et al., 2017), were approximately 0.84 Å because electrons only within the bright-field disk were used due to the low dynamic range and sensitivity of conventional charge-coupled devices (CCDs). Usage of the signal at higher scattering angles beyond the bright-field disk was demonstrated by Humphry et al. (2012) by resolving lattices in gold nanoparticles on a 30-kV SEM. Recently, using a newly developed electron detector with a high dynamic range and speed (Jiang et al., 2018), Jiang et al. achieved an Abbe diffraction-limited resolution of 0.39 Å in 2D MoS₂ at 80 kV, as shown in Fig. 13C–F. Now, the experimental resolution limit relative to the wavelength is reduced to approximately $d = 10\lambda$ ($\lambda = 4$ pm at 80 kV), which outperforms the state-of-the-art electron microscope with aberration correctors. Although in principle the resolution of ptychography is determined by the diffraction limit for the wavelength of the radiation used, thermal diffuse scattering that arises from the vibrations of atoms around their equilibrium positions (lattice vibrations) may ultimately impose the image resolution for the materials being investigated.

Second, electron ptychography offers a more efficient phase contrast transfer function (PCTF) than any other phase imaging techniques used in STEM, such as BF, ABF, or DPC (Yang et al., 2015), as well as high sensitivity to low-Z elements. Being capable of visualizing light and heavier atoms simultaneously, which is a challenging objective for ADF, electron ptychography is becoming a popular method for detecting low-Z atoms in crystals (Wang et al., 2017; Yang et al., 2016b; Wen et al., 2019). Using the direct method of WDD, the work by Yang et al. (2017) resolved Ga-N dumbbells and atomic columns of oxygen in GaN and BiFeO₃ crystals, respectively. Wen et al. (2019) identified C and O surface atoms in a 2D MoS₂ monolayer, and Chen et al. (2019)

Fig. 13 Ultra-high resolution. Atomic resolution image of (A, B) silicon, demonstrating a resolution of 0.136 nm (Nellist et al., 1995) and (C–F) monolayer MoS₂, demonstrating a resolution of 0.39 Å (Jiang et al., 2018).

Fig. 14 Oxygen atoms resolved in CeO₂ by (A) HAADF imaging and (B) ptychographic reconstruction. Boron atoms resolved in LaB₆ by (C) HAADF imaging and (D) ptychographic reconstruction (Wang et al., 2017). located interstitial boron dopants in a Pd lattice. Similarly, using an iterative approach such as ePIE, Wang et al. showed O columns in a CeO₂ crystal and further demonstrated that both boron ($Z_B = 5$) and lanthanum ($Z_{La} = 57$) atomic columns can be resolved simultaneously in the LaB₆ crystal in phase images (Wang et al., 2017), as shown in Fig. 14A–D. Recently, lithium ($Z_B = 3$) atomic columns were visualized in Li-rich cathode materials, as investigated by Lozano et al. (2018) using WDD (Fig. 14E and F). Elements as light as lithium in the periodic table have been clearly visualized in the ptychographic phase at atomic resolution. Given its high phase sensitivity, it can be foreseen that electron ptychography, in the near future, will yield an experimental reconstructed phase at atomic resolution with high phase sensitivity that will be sufficient to detect the lightest element in the universe, hydrogen, in materials such as hydrides.

Third, electron ptychography is robust even under low dose conditions. Unlike STEM ADF and BF imaging (Fig. 1A), which can only detect a small fraction of the transmitted electrons, electron ptychography collects most of the electrons in the diffraction plane (Fig. 1B) so that an image can be formed during the post-acquisition process. Compared to STEM phase imaging methods such as DPC and ABF, ptychography provides the highest signal-to-noise ratio of imaging for weak phase objects (Seki et al., 2018). In addition, ptychography shows better phase images than the equivalent TEM phase images in the presence of partial coherence (Pennycook et al., 2019). Overall, ptychography is a high dose efficiency atomic resolution imaging technique. In earlier work, such as Putkunz et al. (2012), D'Alfonso et al. (2016), and Humphry et al. (2012), the dose of ptychography was set in the range of 10^6 – 10^4 e[−]/Å² to ensure atomic resolutions were achieved with conventional CCDs. The introduction of ultra-fast detectors (Tate et al., 2016; Ballabriga et al., 2013) enabled the usage of focused ptychography to obtain the atomic structural information of lithium oxide battery materials (Lozano et al., 2018) and all-inorganic perovskite solar cells (CsPbBr₃) (dos Reis et al., 2018) without beam damage at a dose of 10^4 – 10^3 e[−]/Å². By using a defocused configuration (Fig. 11B), the dose can be further decreased under certain circumstances, and the reconstruction can be better than that of focused probe geometry at a low dose, as theoretically shown by Jiang et al. (2018). Song et al. (2019) and Chen et al. (2020) experimentally demonstrated high resolution (better than 1.6 Å) at a low dose of ~ 400 e[−]/Å² using defocused electron ptychography on 2D monolayer MoS₂ (Fig. 15A–H) and WS₂, respectively. In terms of algorithm development, Pelz et al. (2017) proposed the use of nonconvex Bayesian optimization to solve the ptychographic phase-retrieval problem. Their theoretical calculations suggested that the dose requirements for imaging biological macromolecules with subnanometer resolution could be satisfied (Fig. 15I–N).

Given that electron ptychography is a technique with ultra-high resolution and high dose efficiency, and is sufficiently sensitive to be able to detect low-Z elements, it provides a promising alternative method for cryo-EM imaging of biological samples. Zhou et al. (2020) demonstrated the first cryo-electron ptychography (Cryo-EPTy) experiments for viral particles imaging, as shown in Fig. 16, and showed that ptychography provides tunable, continuous wideband information transfer, including low spatial frequencies, which is superior to conventional phase contrast imaging. The authors also produced high phase contrast images of viral particles even at a low dose of 5.7 e[−]/Å², and demonstrated the ability to image bio-samples over a wide field of view at the micrometer scale. It can be anticipated that Cryo-EPTy will open a new avenue for high resolution and high contrast structural biological imaging by combining current state-of-the-art single particle analysis (SPA) and tomography in cryo-EM.

Recent advances in technical development

Although ptychography has shown numerous advantages and broad applications, there are still many challenges to tackle. Some of the challenges arise from microscope systems, such as the partial coherence of electron sources and instabilities of scanning systems, and others of which are associated with samples themselves, such as large sample thicknesses and a wide range of spatial frequencies. This section introduces the recent advances in technical development that aim to overcome these issues.

Fig. 16 Cryo-electron ptychography for viral particles imaging at low dose (Zhou et al., 2020).

Multiple states

Partial coherence determines the limit of resolution that can be achieved in both conventional TEM and STEM modes (Nguyen et al., 2014; de Jong and Van Dyck, 1993). Partial coherence also has a critical influence on the quality of ptychographic reconstructed results, as finite spatial coherence weakens the spatial resolution and introduces more artifacts (Stachnik et al., 2015). In recently produced electron microscopes, even though highly coherent electron guns are usually used and the electron probe in ptychographic reconstruction can be assumed to be a pure coherent state under certain circumstances, nonetheless elimination of the incoherence effect is crucial to improve the quality of ptychographic results.

To address this issue, mixed-state ptychography was proposed, and has, as of today, been demonstrated in X-ray (Thibault and Menzel, 2013) and electron ptychography (Cao et al., 2018, 2016). Partial coherence can be considered a combination of a series of

Fig. 17 (A) Idealized optical configuration. (B) Experimental setups; associated datasets were collected using different spot sizes and convergence angles. (C) Orthogonal modes and effective source (right-most tile), the contribution percentage of each mode is labelled above (Cao et al., 2016). Ptychographic reconstructed results of monolayer WS_2 at a dose of $58,000 \text{ e}^-/\text{\AA}^2$; using (D–E) mixed-state ptychography and (F–G) single-state ptychography (Chen et al., 2020).

orthogonal modes, which propagate through optical facilities independently as pure states (Whitehead et al., 2009). Cao et al. (2016) showed that after decomposing the electron probe into a series of orthogonal modes, as shown in Fig. 17C, conventional ptychographic algorithms can be adopted, except that the probe function in the ptychographic reconstruction becomes a combination of different modes. Chen et al. (2020) further compared the reconstructed results from single-state and mixed-state ptychography and showed that the mixed-state approach can potentially improve the quality of the reconstructed result in terms of resolution, dose efficiency, contrast, signal-to-noise ratio, and precision, as shown in Fig. 17D–G. Because ptychography is also able to account for many of the different factors that result in decoherence-like effects in measured diffraction patterns, such as a finite electron source size, chromatic aberration, sample vibration, and rapid instabilities of the image-forming system, use of a mixed-state approach is greatly beneficial for ptychographic reconstructions.

Probe position errors

Ptychography does not rely on high-quality lenses; instead, the resolution and accuracy of the resultant reconstructions are limited by the precision with which the electron probe positions can be measured with respect to the sample, as shown in Fig. 11 (Maiden et al., 2012b). Simulation work by Hue et al. (2011) showed that even a small error in the probe position has a strong influence on the reconstruction, with probe position errors creating a mesh pattern that can lead to incorrect overall solution. Therefore, the accuracy of the probe position is crucial for producing high-quality ptychographic reconstructions.

Due to thermal drift and hysteresis in the probe scanning coils, errors in the probe position are inevitable. When using a well-controlled scanning system, the errors caused by hysteresis in the scanning coils can be reduced; yet, the thermal drift of the sample remains. As a result, the integration of post-processing position-correction algorithms into ptychographic iterations becomes increasingly necessary and essential for high-resolution reconstructions.

A number of position-correcting methods have been developed for ePIE and DM. For example, Maiden et al. proposed the position-correcting ptychographic iterative engine (pcPIE) (Maiden et al., 2012b), which integrates a set of position correction

vectors into the inaccurately measured positions compared to conventional ePIE. Zhang et al. proposed unknown-position ePIE (Xu et al., 2020), which uses normalized root-mean-square-error (NRMSE) as an indicator for identifying drift points and automatically adjusts the feedback parameters. An approach based on optimization with respect to the summed-square error was also applied to the DM algorithm (Beckers et al., 2013). Using a gradient-descent-based algorithm (Guizar-Sicairos and Fienup, 2008), the object, the illumination beam, and the translation parameters can be jointly optimized.

Multiple scattering

Fundamentally ptychography is based on a 2D multiplicative approximation to model the interaction of the probe and the object, which assumes that the exit wave is the product of the probe function and the object transmission function (Eq. (1)). However, this approximation breaks down at modest specimen thicknesses due to their larger interaction cross-section with the electron beam, which causes significant multiple scattering events to occur. As a result, to minimize multiple scattering, the illumination should be optimized and a suitable sample thickness should be employed to obtain a reasonable reconstruction (Liu et al., 2009).

To overcome this issue, Maiden et al. (2012a) adapted a multislice approach (Kirkland, 1998; Cowley and Moodie, 1957) that is widely used to account for multiple scattering events in image simulations and incorporated an inverse multislice (invMS) method into ptychographic reconstruction algorithms, whereby the exit surface wave function of an object is calculated slice by slice using a series of multiplications and Fresnel propagations between the slices as the wave is transmitted through the sample.

This invMS ptychography has been implemented in visible light (Godden et al., 2014) and X-ray imaging (Suzuki et al., 2014; Tsai et al., 2016). In electron microscopy, Gao et al. (2017) found that this method can provide depth-sectioned information from a 3D complex transmission function of a thick sample (Fig. 18A–H). Recently, Chen et al. (2021) recovered a linear phase response versus thickness and pushed the lateral resolution close to the intrinsic atomic size, limited by the thermal fluctuations of the atoms themselves (Fig. 18I–L). InvMS electron ptychography provides a powerful tool for determining the 3D structures of crystalline samples, for example, locating single dopants.

Low-frequency information transfer

Objects (cells, proteins, particles, etc.) naturally tend to contain information at many different spatial scales (or frequencies) from very fine (atomic lattice) to very coarse (overall shape). The goal of an ideal imaging system is to form an image that contains information from all scales simultaneously. The CTF describes how information is transferred at different frequencies through optical systems (Wade, 1992).

Compared to defocused phase-contrast TEM, ptychography has a wider, tunable, and continuous CTF in which either direct solutions (O’Leary et al., 2021; Yang et al., 2015) (Fig. 19A) or iterative approaches (Zhou et al., 2020) (Fig. 19D) are used for weak phase objects. In general, there are no zero crossings in the CTF such that contrast reversals are completely avoided at varying defocus conditions, which allows the phase to be directly interpretable. The bandpass of the CTF in the spatial frequency domain can also be tuned by adjusting the convergence angle, α , which enables information of low and high spatial frequencies to be transferred in a controllable manner. One can simply decrease α to enhance information transfer in the low-frequency region, thereby improving overall contrast without inducing rapid oscillations in the CTF at high frequencies and causing resolution degradation. Unlike phase contrast TEM, the method of contrast enhancement by varying α does not sacrifice resolution, which has been a major limitation of defocused phase contrast TEM imaging used in cryo-EM.

Another method of contrast enhancement is to introduce a prespecimen phase plate in the probe forming aperture in STEM to form 4D-STEM data with a focused probe. This approach is called ptychographic matched illumination detector interferometry STEM (PMIDI-STEM) (Yang et al., 2016a). By combining with noniterative ptychography, PMIDI-STEM enables an improved enhancement of the contrast transfer at low spatial frequencies for 2D imaging. The advantage of contrast enhancement using ptychography is particularly important for biological cryo-EM imaging because low spatial frequencies are inaccessible using conventional phase-contrast imaging (as shown in Fig. 19E–G).

Conclusion: Multidimensional ptychography

Electron ptychography has been successfully applied in reconstruction of the 2D phase information of object transmission functions. This method has many advantages, such as higher resolution and better signal-to-noise ratio, and it is more sensitive to low-Z elements than conventional imaging methods. In the future, the capabilities of electron ptychography can be further extended to other dimensions, such as the third dimension, time, and energy domains, as shown in Fig. 20.

TEM images are 2D projections of 3D objects, which in some cases makes the interpretation of the results difficult without information pertaining to the third dimension (optical axis). The most widely used 3D imaging methods are electron tomography (ET) (Baumeister et al., 1999; Midgley and Dunin-Borkowski, 2009) and SPA (Henderson and Unwin, 1975; Unwin and Henderson, 1975), which have played vital roles in 3D imaging for materials and biological science.

The combination of ptychography and tomography has been experimentally demonstrated with X-ray (Diaz et al., 2014; Holler et al., 2014, 2017; Dierolf et al., 2010; Chen et al., 2013) and electron beams (Ding et al., 2022). As ptychography can provide each projected image with a higher resolution that can be used as input data for tomography, both in-plane and out-of-plane resolutions

Fig. 18 Multislice ptychography method used for reconstructing three-dimensional information of (A–H) carbon nanotubes (CNTs) (Gao et al., 2017) and (I–L) crystalline PrScO_3 (Chen et al., 2021).

Fig. 19 (A) Phase contrast transfer functions (PCTFs) of ptychography using the SSB algorithm for various convergence semiangles were calculated. (B) and (C) show the ptychographic reconstructed results under convergence semiangle of 31.5 mrad and 7.5 mrad, respectively (O'Leary et al., 2021). (D) Simulated PCTFs of ptychography using the ePIE algorithm for various convergence semiangles. Poisson noise was added. (E–G) Experimental reconstructed phase results of adenovirus with convergence semiangle of 1.37, 4.68, and 10 mrad (Zhou et al., 2020).

can be improved. In particular, with the advantage of high contrast and high dose efficiency, electron ptychographic tomography holds great promise for the high-resolution 3D structural imaging of biological and nonbiological components simultaneously, which has been a great challenge for TEM tomography due to the inherently low contrast of biological components.

In light of recent 2D high-contrast Cryo-EPTy work performed on viral particles (Zhou et al., 2020), ptychographic SPA (Pei et al., 2021; Pei et al., 2023) could help reduce the particle numbers required for 3D reconstruction and facilitate 3D classification of bio-structures of either low concentration or low symmetry.

With a pulsed electron beam source and ultrafast detector, single-shot and dynamic TEM have been designed and implemented to study dynamics in condensed matter systems and biological processes with micro- to attosecond temporal resolution. However, owing to the nature of the scanning mode and the limited read-out speed of detectors, the temporal resolution of ptychography remains poor. The limitations of ptychography have stimulated attempts to develop time-resolved methods in recent years.

Fig. 20 Schematic illustration of future ptychography.

Single-shot ptychography was proposed for light optics (Sidorenko and Cohen, 2015), whereby instead of scanning the specimen point by point, pinholes are used to form multiple probe beams and illuminate the specimen simultaneously with partial overlap between neighboring illuminated areas so that ptychographic datasets are collected in a single exposure. Based on this, time-resolved imaging by multiplexed ptychography was developed for rapid dynamic imaging with pulsed laser beams (Wengrowicz et al., 2019; Sidorenko et al., 2017). In electron optics, the multiple electron beam system has been used to increase the throughput of microscopy and lithography applications. Therefore, based on current techniques, the integration of a multiple electron beam source with ptychography would be possible, which would facilitate time-resolved electron ptychography with a pulsed electron beam for dynamical studies both in the materials and life sciences.

Electrons can interact either elastically or inelastically with a sample, and the inelastically scattered electrons contain a wealth of information, such as the chemistry, band structure, and dielectric properties of the sample. Due to the constraints of detector geometry in electron ptychography, the inelastically scattered electrons in the energy-loss domain cannot be accessed.

A new “hollow” detector was devised, as shown in Fig. 20, to enable electron ptychography to couple with existing EELS designs to provide structural and elemental information simultaneously. Once dedicated “hollow” pixelated STEM detectors are commercially available, the configuration of “hollow”-type ptychography (Song et al., 2018) with EELS and other 4D-STEM (Ophus, 2019) capabilities (Fig. 20) will likely be widely used, becoming a powerful tool for the collection of multichannel signals and extraction of multidimensional information from samples.

Big data and artificial intelligence (AI) are at the forefront of technological advances in the digital world. Ptychography itself is a data-driven microscopic technique that can be further integrated with AI and machine learning (Nguyen et al., 2018; Wengrowicz et al., 2020; Guan and Tsai, 2019), for example, to obtain better reconstruction results using considerably less time (Kappeler et al., 2017). With the rapid generation of vast datasets across a range of multiple dimensions, permitted by continuous advances in EM instrumentation, AI-enhanced electron ptychography will emerge as one of the potentially disruptive themes in electron microscopy underpinning materials development for quantum computing, renewable energy, and the life sciences.

Abstract

Momentum-resolved scanning transmission electron microscopy (MR-STEM) refers to the recording of a full diffraction pattern for each scan point of a scanning electron probe. The resulting four-dimensional datasets not only overcome the limited flexibility of established detector geometries determined by hardware but also transform formerly challenging methods into widespread imaging modes. After briefly reviewing multidimensionality aspects in STEM, a unique terminology for MR-STEM is introduced. The concept of first-moment STEM (FM-STEM) is derived robustly from fundamental quantum mechanics, followed by a detailed description of practical aspects related to ultrafast pixelated detectors. FM-STEM delivers the average lateral momentum of the electron beam. The article works out how atomic electric fields can be measured in thin specimens, and outlines methodologies for measuring polarization-induced electric fields in thick ones. By angular multirange analysis, it is elucidated how MR-STEM can yield specimen thickness and composition simultaneously. A brief assessment of inelastic scattering effects on MR-STEM closes this article.

Key points

This article provides the following concepts:

- Introduction to multidimensionality in STEM.
- Establishing momentum-resolved STEM as a versatile four-dimensional imaging technique.
- Mathematical derivation and experimental demonstration of momentum transfer mapping based on first-moment STEM.
- Atomic and polarization-induced electric field measurements by employing Ehrenfest's theorem.
- Angle-resolved STEM concept to separate local composition, thickness, and strain effects in an angular multirange analysis.
- Discussion of the impact of inelastic scattering on momentum-resolved STEM.
- Future prospects.

Introduction

Scanning transmission electron microscopy (STEM) has recently crossed the border to probe subatomic details thanks to aberration correction. At such length scales, partly reaching down below 50 pm, formerly paradigmatic questions as to chemical composition

or lattice strain become secondary, in favor of studying electric properties with sub-bond-length resolution. In fact, the dramatic improvement of the spatial resolution is only one of several prerequisites to address these challenges because established detection and evaluation schemes provide insufficient information.

On the hardware side, ultrafast cameras led to a revolution of standard STEM acquisition in that a full diffraction pattern can be recorded at each scan point of the probe. This unique combination of real- and diffraction space information constitutes the focus of this article, momentum-resolved STEM (MR-STEM).

A paramount requirement to profit from the new wealth of available data is the development of methods to draw scientific conclusions about local physical properties such as electrostatic fields, potential, charge distributions, polarization, as well as chemical composition and structure.

To stay within the scope and maintain complementarity to the other chapters of this volume, this article covers the most important *direct* and *contemporary* methodologies. In particular, MR-STEM is introduced as a generic setup, before first moment imaging, electric field, potential and charge density mapping, polarization measurement, and composition quantification by angular multirange analysis are presented in detail. The impact of inelastic scattering on these methods is shortly discussed.

Electron ptychography concepts and related phase retrieval schemes, which are also based on momentum-resolved data, will not be discussed in this article. The reader is referred to pertinent literature to study those. Similarly, this document excludes methods that draw information from the geometry of diffraction patterns, such as strain and electric field measurements by nano-beam electron diffraction, which are well-represented in existing literature.

Multidimensionality in STEM

By shifting a focused beam and thereby subsequently probing different volumes of a specimen, STEM is inherently capable of simultaneously delivering a multitude of signals at high spatial resolution. Besides the two real-space dimensions of the scan, *multidimensionality* in STEM is an ambiguous term that can include energy-dispersive X-ray (EDX) or electron energy loss spectra (EELS), secondary or back-scattered electron signals, as well as cathodoluminescence data, to name a few established detection schemes. Most importantly, STEM originally employs detectors positioned in the Fraunhofer diffraction plane covering different portions of solid angles. The most prominent imaging modes are bright- and annular dark field (BF, ADF) STEM as depicted in Fig. 1. They employ disk or ring-shaped detectors centered around the optical axis and deliver coherent and incoherent scattering details, respectively. By segmenting (annular) BF detectors, differential phase contrast (DPC) (Dekkers and de Lang, 1978) STEM constitutes a long-standing tradition in providing contrast due to magnetic (Chapman et al., 1978), electric (Lohr et al., 2012; Shibata et al., 2012), and weakly scattering features (Rose, 1977; Lazić et al., 2016; Lazić et al., 2022).

Fig. 1 Scanning transmission electron microscopy (STEM) setup and detection schemes. In aberration-corrected STEM, an electron probe is focused to subatomic diameter and rastered across the specimen. In momentum-resolved STEM (MR-STEM), a full diffraction pattern is recorded at each scan point, yielding a four-dimensional data set. This drastically enhances versatility of the STEM technique as compared to conventional bright field (BF), annular dark field (ADF) or differential phase contrast (DPC) imaging employing much simpler detector geometries.

Momentum-resolved STEM

Given the versatile physical insights dedicated detector geometries offer as to the local chemistry, electrical, magnetic, and structural properties, it is a natural advancement to record the data *momentum-resolved*. This means that a detailed diffraction pattern is recorded at each scan point which allows for maximum flexibility to generate any dedicated contrast a posteriori during the evaluation using software. As illustrated in Fig. 1, the momentum-resolved imaging mode hence produces a four-dimensional dataset $I(\vec{R}, \vec{p}_\perp)$ consisting of two raster coordinates $\vec{R}$ of the probe in real space, and two diffraction coordinates $\vec{p}_\perp$, which is why this imaging mode is occasionally referred to as *4D STEM*.

Obviously, a critical requirement to put any STEM technique into practice is the availability of high-speed detectors, as the dwell time per raster point is given by a detector's minimal exposure time. For example, a conventional ADF STEM detector is commonly read out at MHz rates. Although charge-coupled devices (CCDs) emerged in the late 1980s (Spence and Zuo, 1988), frame rates remained in the few-Hz range for decades, and allowed for rather conceptual proofs (Rodenburg et al., 1993) than practical applications. First ultrafast CCD-based cameras with kHz frame rates were introduced to STEM in 2012 (Müller et al., 2012), quickly followed by a variety of technologies in the coming years (Plackett et al., 2013; Müller-Caspary et al., 2015; Tate et al., 2016; Jannis et al., 2022; Ryll et al., 2016). Acquisition speeds rapidly increased to frame rates of several kHz, thus putting a variety of new diffraction-based STEM methods into practice which are based on momentum-resolved data acquisition.

Terminology

The multitude of accessible dimensions renders the term *4D STEM* rather ambiguous. Therefore, *scanning diffraction* or MR-STEM specifies the physical dimensions more accurately, and the latter term will be used throughout this article. MR-STEM is a broad term that describes any experiment where diffraction patterns are recorded at sufficiently high sampling in momentum space as a function of the position of a scanning STEM probe.

We will elucidate the significance of *first moment STEM* (FM-STEM) for the average momentum transferred to the electron beam by virtue of the interaction with electric fields below. FM-STEM refers to the first moment of the scattered intensity distribution (Waddell and Chapman, 1979) at each scan point, which is identical to the average momentum (transfer) occurring in the specimen. It is also called *center of mass* (COM) imaging. These two terms often appear in conjunction with, but need to be distinguished from direct electric or magnetic field mapping, which is only reliable if certain conditions are fulfilled, as will be detailed below.

In the style of rotationally symmetric BF and ADF detectors, the 2π -azimuthal integrals of diffracted intensities taken in dependence of the scattering angle ϑ are subject to *angle-resolved STEM* (AR-STEM). Strain, chemical composition, specimen thickness, or inelastic scattering can leave unique fingerprints in the radial intensity that can be used for the characterization of specimens via the comparison with simulations.

Fig. 2 depicts the three coordinate frames used in this work. Capital $\vec{R} = (X, Y)$ denotes the scan coordinate in a 2D plane perpendicular to the optical axis. The STEM probe might exhibit a defocus Δf measured perpendicular to $\vec{R}$ with $\Delta f < 0$ inside the specimen. Fourier-transforming a measured signal with respect to $\vec{R}$ provides its representation in terms of spatial frequencies of the scan denoted by $\vec{Q} = (U, V)$. Positions inside the specimen, for example, atom positions or the positions on which electric field and electrostatic potential depend, are given by real-space coordinates $\vec{r} = (x, y, z)$. Fourier-transforming in 2D with respect to

Fig. 2 The coordinate systems used in this article: x and y are used as lateral real-space coordinates perpendicular to the optical axis while z measures position in beam direction. Positions inside the specimen are therefore given by $\vec{r} = (\vec{r}_\perp, z) = (x, y, z)$. $\vec{r}_\perp$ gives the lateral component. $\vec{q}_\perp = (u, v)$ is the related reciprocal coordinate, that is used in the diffraction pattern. The position of the probe, measured in the x - y -system, is denoted as $\vec{R} = (X, Y)$.

$\vec{r}_\perp = (x, y)$ yields the conjugate diffraction coordinate system with spatial frequency vector $\vec{q}_\perp = (u, v)$ perpendicular to the optical axis, and the respective momentum $\vec{p}_\perp = h \cdot \vec{q}_\perp$ with Planck's constant h . The momentum transfer is related to the scattering angle by $p_\perp = h\lambda^{-1} \sin \vartheta \approx h\lambda^{-1} \vartheta$ with the electron wavelength λ and the approximation being valid for small angles.

A momentum-resolved STEM example

The versatility of MR-STEM is demonstrated by means of an experimental atomically resolved scan of an AuPd nanowire in Fig. 3. The scan covers 255×130 scan pixels and consists of 33150 diffraction patterns recorded in 26 s, of which one is shown in Fig. 3A. As an inset, the azimuthal integral is depicted for this particular scan point, being the basis for AR-STEM. Integrating intensity inside the Ronchigram yields the BF signal in (B), and taking only the central pixel delivers Fig. 3C. This can be considered equivalent to a conventional TEM image acquired under parallel illumination according to the theorem of reciprocity (Cowley, 1969; Krause and Rosenauer, 2017). Note that this is an aberration-corrected CTEM image acquired without a corrector for the imaging unit of the microscope. Different evolution of chemical and structural contrast in dependence of the detector acceptance angles becomes obvious from the low-angle ADF (LAADF) and the high-angle (HAADF) images in Fig. 3D and E.

Whereas, in principle, data in Fig. 3A–E are available also without an MR-STEM setup, Fig. 3F maps the first moment vector field color-coded. As will be shown below, the FM-STEM signal reflects the momentum transfer $\langle \vec{p}_\perp \rangle$, which points toward the atomic nuclei for scan points close to an atom due to the positive charge of the nucleus, being only partially screened by the electrons there. That atoms are sinks of momentum transfer is obvious from Fig. 3G, where $\text{div} \langle \vec{p}_\perp \rangle$ is shown. In sufficiently thin specimens, Figs. 3F and G are proportional to the projected electric field and charge density, respectively.

First-moment STEM

Theory and methodology

For each scan position $\vec{R}$ a real-space exit wave $\psi(\vec{r}_\perp, \vec{R})$ is present at the exit face of the specimen. FM-STEM targets the measurement of the average transverse momentum of this wave. Therefore, the expectation value $\langle \vec{p}_\perp(\vec{R}) \rangle$ is of central importance, which can be calculated in two equivalent ways. Firstly one can calculate the real-space integral

$$\langle \vec{p}_\perp(\vec{R}) \rangle = -i\hbar \iint_{-\infty}^{\infty} \psi^*(\vec{r}_\perp, \vec{R}) [\vec{\nabla}_\perp \psi(\vec{r}_\perp, \vec{R})] dxdy, \quad (1)$$

which involves the (lateral) momentum operator $-i\hbar \vec{\nabla}_\perp$ acting as a gradient on the complex wave function, which is not observable. ψ^* denotes the complex conjugate of ψ . Secondly, the transition to momentum space can be made, where the momentum operator takes the simple form of the vector $h\vec{q}_\perp$. Then the expectation value reads

$$\begin{aligned} \langle \vec{p}_\perp(\vec{R}) \rangle &= h \iint_{-\infty}^{\infty} \tilde{\psi}^*(\vec{q}_\perp, \vec{R}) \vec{q}_\perp \tilde{\psi}(\vec{q}_\perp, \vec{R}) dudv \\ &= h \iint_{-\infty}^{\infty} \tilde{\psi}^*(\vec{q}_\perp, \vec{R}) \tilde{\psi}(\vec{q}_\perp, \vec{R}) \vec{q}_\perp dudv \\ &= h \iint_{-\infty}^{\infty} |\tilde{\psi}(\vec{q}_\perp, \vec{R})|^2 \vec{q}_\perp dudv, \end{aligned} \quad (2)$$

Fig. 3 Momentum-resolved STEM experiment (Au nanowire). A diffraction pattern as in (A) is recorded at each raster position in STEM. The inset shows the azimuthal average forming the basis for AR-STEM. (B) Bright field image from integrating the whole Ronchigram. (C) Image formed by the central pixel of the Ronchigram only, being equivalent to a CTEM image by reciprocity. (D, E) Low- and high-angle ADF images. (F) First moment showing the local momentum transfer and (G) divergence of the momentum transfer, showing atoms as sinks of the vector field in (F). The data have been recorded with a Medipix3 detector with 256×256 camera pixels at 120 keV.

with $\vec{\psi}(\vec{q}_\perp)$ denoting the 2D Fourier transform of $\psi(\vec{r}_\perp)$ with respect to x, y . $|\vec{\psi}(\vec{q}_\perp, \vec{R})|^2$ is the probability density to detect an electron at diffraction coordinate $\vec{q}_\perp$ with the STEM probe at position $\vec{R}$. It is identical to the normalized diffraction intensity $I(\vec{q}_\perp, \vec{R})$ so that Eq. (2) can be written as

$$\langle \vec{p}_\perp(\vec{R}) \rangle = h \iint_{-\infty}^{\infty} \vec{q}_\perp I(\vec{q}_\perp, \vec{R}) d\vec{q}_\perp, \quad (3)$$

which is more intuitive and states the central relation for FM-STEM.

The integrals in Eq. (3) equal the first moment of $I(\vec{q}_\perp, \vec{R})$, or simply its COM. The expectation value of the momentum is hence related to the diffraction pattern by this straightforward mathematical operation and it is due to this relation that FM-STEM is oftentimes referred to as COM. The expression (3) is exact and condenses the possibly very complex intensity distribution in diffraction space to a single vector with fundamental physical meaning.

Practical aspects

Eq. (3) means that the first moment in diffraction space is a robust measure of the average lateral momentum $\langle \vec{p}_\perp(\vec{R}) \rangle$. This is rather a fundamental statement from basic quantum mechanics than being a specific STEM measurement methodology. However, translating these theoretical considerations to the experiment one can see that recording diffracted intensities in MR-STEM provides access to the average momentum transferred to the electron beam by the specimen.

An actual MR-STEM setup records the diffraction pattern only up to a cutoff frequency q_c , usually on a discrete pixel array. Therefore, Eq. (3) is in practice approximated by

$$\langle \vec{p}_\perp(\vec{R}) \rangle \approx h \sum_{q_\perp \leq q_c} \vec{q}_\perp I(\vec{q}_\perp, \vec{R}) \quad (4)$$

for a discretely sampled normalized $I(\vec{q}_\perp, \vec{R})$. FM-STEM has initially been mentioned conceptually in the 1970s by Waddell and Chapman (Waddell and Chapman, 1979). However, the realization of Eq. (4) employed typically only four segments for practical reasons, leading to the DPC setups with annular or disk-shaped detectors divided into four segments. In this regard, FM-STEM is the natural evolution of the traditional DPC techniques, making full use of the exhaustive detail of an MR-STEM measurement.

The approximate character of Eq. (4) should be kept in mind when selecting experimental parameters. First, given a certain camera hardware, the camera length determines the cutoff q_c and the reciprocal space sampling. Fortunately, it was shown that the sum in Eq. (4) converges very quickly, typically at spatial frequencies well below twice the Ronchigram radius (Müller-Caspary et al., 2016). The reason for this is that thermal diffuse scattering (TDS) makes the dominant contribution for high angles at room temperature, but does not contribute to the first moment significantly (Müller et al., 2014; Winkler et al., 2020).

Second, if $I(\vec{q}_\perp, \vec{R})$ is only sampled discretely, the pixel size has impact on the precision. However, a few tens of pixels along the Ronchigram diameter suffice in many cases, but this depends on the intended precision and used dose. Some nonpixelated detection schemes exist in the style of position-sensitive detectors (Müller-Caspary et al., 2015) or direct first moment detectors (Schwarzhuber et al., 2018).

Third, $I(\vec{q}_\perp, \vec{R})$ was defined normalized. Therefore, attention needs to be drawn to the normalization of experimental MR-STEM data. Denoting the raw measured signal by $J(\vec{q}_\perp, \vec{R})$, there has to be some normalization scheme

$$I(\vec{q}_\perp, \vec{R}) = \frac{1}{J_0} J(\vec{q}_\perp, \vec{R}). \quad (5)$$

Following Eqs. (3), (4), and (5), the normalization factor J_0 has to be chosen in such a way that $I(\vec{q}_\perp, \vec{R})$ is the probability density of detecting an electron with lateral momentum $h\vec{q}_\perp$. In the strict sense, this normalization can only be performed accurately if all electrons are detected, that is, if q_c in Eq. (4) is large enough to include the total scattered intensity. In practice, however, J_0 can only be calculated from recorded and hence limited diffraction patterns. Electrons having been scattered beyond the detector are missing especially at high camera lengths or in strongly scattering regions of the specimen. Usually,

$$J_0 = \sum_{q_\perp \leq q_c} J(\vec{q}_\perp, \vec{R}) \quad (6)$$

is just calculated from the diffraction patterns themselves, implicitly assuming that the first moment of all unrecorded electrons is the same as that of the recorded ones. This assumption usually holds true, especially if q_c is chosen sufficiently large. Note that in this case J_0 can also vary throughout the different raster points an MR-STEM dataset. To sum up the previous three aspects, it is advisable to minimize errors by choosing a camera length that maximizes q_c while maintaining sufficiently dense sampling of the bright field region to which the first moment is most sensitive.

A fourth aspect of FM-STEM experiments results from the vectorial nature of $\langle \vec{p}_\perp(\vec{R}) \rangle$ and is purely geometrical. The first moment of the diffraction pattern is determined within the coordinate frame of the pixel array of the camera, and then mapped against the scan position $\vec{R}$ to display and analyze this vector field. Because the scan frame can be rotated arbitrarily in STEM according to, for example,

Fig. 4 Relative rotation of scan and diffraction frame. For the vectorial analysis of MR-STEM data, for example, for FM-STEM, a potential rotation between the coordinate frames for $\vec{R}$ and $\vec{q}_\perp$ needs to be accounted for; otherwise a radial field (A) appears falsely as a rotational one in (B).

the specimen geometry, a correction of the relative rotation between the different coordinate systems is necessary in nearly all cases (Zweck et al., 2023). Note that missing this aspect can turn a radial field into a curl field as schematically demonstrated in Fig. 4.

Fifth, besides the rotation, the origin of $\vec{q}_\perp$ is crucial. Choosing it in such a way that the first moment of the incoming electron beam is zero, it equals the average momentum transferred to the probe via interaction with the specimen, as implicitly assumed in the terminology above already. A practical way to determine the origin is to acquire an additional MR-STEM scan without any specimen taken under otherwise identical conditions, and to subtract it from the actual measurement so as to also remove any potential movement of the diffraction pattern induced by the scan engine.

Mapping electrical properties

Basic concept

For any quantum mechanical operator $\hat{o}$, the time evolution of its expectation value is given by the Ehrenfest theorem,

$$\frac{d}{dt} \langle \hat{o} \rangle = \frac{i}{\hbar} \langle [\hat{H}, \hat{o}] \rangle + \left\langle \frac{\partial \hat{o}}{\partial t} \right\rangle, \quad (7)$$

including the Hamiltonian $\hat{H} = \frac{\hat{p}_\perp^2}{2m_e} - e\hat{V}(\vec{r})$ with electron mass m_e , elementary charge e , and the potential $\hat{V}$. For the static case and $\hat{o} = \hat{p}_\perp$

$$\left\langle \frac{\partial \hat{p}_\perp}{\partial t} \right\rangle = 0, \quad (8)$$

as well as

$$[\hat{p}_\perp^2, \hat{p}_\perp] = [\hat{p}_\perp \hat{p}_\perp, \hat{p}_\perp] = \hat{p}_\perp [\hat{p}_\perp, \hat{p}_\perp] + [\hat{p}_\perp, \hat{p}_\perp] \hat{p}_\perp = 0. \quad (9)$$

The remaining commutator in Eq. (7) reads, in real-space representation and after applying the product rule for $\vec{\nabla}_\perp$ acting on the product of $\hat{V}$ and ψ :

$$\left[-e\hat{V}(\vec{r}), \frac{\hbar}{i} \vec{\nabla}_\perp \right] = e \frac{\hbar}{i} \vec{\nabla}_\perp \hat{V}(\vec{r}) = -e \frac{\hbar}{i} \vec{E}_\perp. \quad (10)$$

It was used that, in electrostatics, the negative gradient of the potential equals the electric field $\vec{E}$, here considering only lateral components. Inserting Eq. (10) into Eq. (7) gives

$$\frac{d\langle \vec{p}_\perp \rangle}{dt} = -e \langle \vec{E}_\perp \rangle. \quad (11)$$

In a semiclassical picture, the beam electrons move along the z -direction with a velocity of

$$v_e = \frac{h}{\lambda m_e \gamma}, \quad (12)$$

where γ is the relativistic Lorentz factor and m_e is the mass of the electron. This allows for the substitution $dz = v_e dt$ within the time interval dt , yielding

$$d\langle \vec{p}_\perp \rangle = -\frac{e}{v_e} \cdot \langle \vec{E}_\perp \rangle dz. \quad (13)$$

This fundamental relation can also be derived rigorously in quantum mechanical manner within the paraxial approximation. Integrating both sides and explicitly writing the xy integral $\langle \vec{E}_\perp \rangle$ results in

$$\begin{aligned} \langle \vec{p}_\perp \rangle &= -\frac{e}{v_e} \cdot \int_{-\infty}^{\infty} \langle \psi | \vec{E}_\perp | \psi \rangle dz \\ &= -\frac{e}{v_e} \cdot \iiint_{-\infty}^{\infty} \vec{E}_\perp(\vec{r}) \cdot |\psi(\vec{r})|^2 dx dy dz. \end{aligned} \quad (14)$$

We have thereby gained a direct relation between field and momentum transfer. However, both $\vec{E}_\perp$ and the squared wave function depend on all three specimen coordinates, and the intensity distribution inside the specimen is generally not known. Eq. (14) states that the lateral momentum transfer is essentially determined by weighting the local lateral field components $\vec{E}_\perp$ with the local squared wave function, being proportional to the intensity. Critically, $\vec{E}_\perp$ and ψ are not independent from each other: Potential gradients due to, for example, the presence of atoms, shape the wave function possibly heavily on its propagation through the specimen, as is known from Bloch wave (Bethe, 1927) or multislice (Cowley and Moodie, 1957) solutions of the Schrödinger equation.

Until here the derivation was exact, but in order to separate field and intensity from each other, at least with respect to the z -integration along the electron beam direction, either prior additional knowledge of the beam propagation is required, or approximations need to be made. For optically very thin objects, one can neglect any change of the probe intensity in direct space, that is, assume that the shape of the probe intensity does not change while going through the specimen. Mathematically this approximation manifests in $|\psi(\vec{r})|^2 \approx |\psi(\vec{r}_\perp)|^2$ for all z -coordinates. The z -integration in (14) then involves $\vec{E}_\perp(\vec{r})$ only and yields

$$\langle \vec{p}_\perp \rangle \approx -\frac{e}{v_e} \cdot \iint_{-\infty}^{\infty} \vec{E}_\perp^P(x, y) \cdot |\psi(\vec{r}_\perp)|^2 dx dy \quad (15)$$

with the projected electric field

$$\vec{E}_\perp^P(x, y) := \int_{-\infty}^{\infty} \vec{E}_\perp(x, y, z) dz, \quad (16)$$

usually measured in units of Volts because of the z -integration.

So far, the derivation comprised an arbitrary wave function and did not incorporate the scanning concept. The normalized intensity $I_P(\vec{r}_\perp)$ of the coherent probe, centered on the optical axis, can be calculated if the shape and the position of the probe-forming aperture, as well as the aberrations are known. The scanning process shifts this probe by $\vec{R}$ such that the intensity reads

$$|\psi(\vec{r}_\perp, \vec{R})|^2 = I_P(\vec{r}_\perp - \vec{R}), \quad (17)$$

which can be inserted in Eq. (15) to obtain

$$\begin{aligned} \langle \vec{p}_\perp(\vec{R}) \rangle &\approx -\frac{e}{v_e} \iint_{-\infty}^{\infty} I_P(\vec{r}_\perp - \vec{R}) \vec{E}_\perp^P(\vec{r}_\perp) dx dy \\ &= -\frac{e}{v_e} I_P \star \vec{E}_P. \end{aligned} \quad (18)$$

This central equation relates the measured momentum transfer $\langle \vec{p}_\perp \rangle$ in Eqs. (3) and (4) to the lateral electric field $\vec{E}_\perp^P$, projected along beam direction, by a formal cross-correlation $\star$ with I_P the intensity of the STEM probe. This can be understood intuitively, too: The first moment measured in thin specimens is directly proportional to the electric field broadened by the probe shape. With very small probes realizable thanks to aberration correction, this can be an excellent tool to measure fields down to the subatomic scale. In a further derivation within the framework of the phase object approximation, it can also be shown that the average momentum transfer is similarly proportional to the gradient of a phase object (Winkler et al., 2020; Müller-Caspary et al., 2017).

The result in Eq. (18) deserves several remarks. First, the cross-correlation with the probe intensity puts a limit to the spatial resolution for the measurement of $\vec{E}_\perp^P$. Second, the probe intensity is the governing quantity, rather than the wave function as would be the case for other BF-STEM techniques or electron ptychography. Third, FM-STEM-based electric field mapping as derived here puts DPC STEM on an accurate basis as long as, forth, dynamical scattering and propagation can be neglected. This aspect involves the thickness, composition, and crystallographic orientation of the specimen, the acceleration voltage, convergence angle of the STEM probe determined by $A(q_\perp)$ and aberrations $\chi(q_\perp)$. Consequently, no general rule can be given up to which thickness Eq. (18) retains a desired accuracy. In a gold crystal, FM-STEM results as in Fig. 3F would not allow for a quantifiable conversion to electric fields anymore, whereas long-range electric stray fields in vacuum can extend hundreds of nanometers along z before Eq. (18)

becomes inaccurate. Fifth, real-space averaging strategies have been developed to separate long-range polarization fields in crystals from atomic contributions (Müller-Caspary et al., 2019), as will be outlined below. Despite the analytical clarity of Eqs. (2) and (4) it is nevertheless advisable to conduct dynamical simulations to investigate the impact of microscope and specimen parameters, and multiple scattering.

Partial coherence

Until now the fully coherent case was considered. However, when comparing real FM-STEM-based electric field measurements with simulations in well-defined systems such as mono-/bilayer 2D materials, it turns out that cross-correlating the electric field with the normalized probe intensity I_p yields too sharply peaked electrical fields. In that respect, partial spatial and temporal coherence need to be taken into account.

In STEM, partial spatial coherence results in an incoherent broadening of the probe. To account for it, one needs to calculate the momentum transfer $\langle \vec{p}_\perp \rangle$ according to Eq. (15) for different probe positions $\vec{R}_\perp$ and form an average weighted by the effective source extent $w_s(\vec{R}_\perp)$.

Partial temporal coherence can similarly be included by calculating $\langle \vec{p}_\perp \rangle$ for various probe defoci Δf and forming a weighted average according to the defocus spread $w_t(\Delta f)$.

Looking closely at Eq. (15), we realize that only I_p depends on $\vec{R}$ and Δf . Hence both the temporal and spatial averaging can be pulled into the correlation integral and only be applied to the probe intensity. Partial coherence can thus be elegantly included into Eq. (15) by simply replacing the totally coherent probe intensity with

$$I_{PC}(\vec{r}_\perp) = \iiint I_p(\vec{r}_\perp - \vec{R}, \Delta f) \times w_s(\vec{R}) w_t(\Delta f) dX dY. \quad (19)$$

Note that I_{PC} is the actual probe intensity incident on the specimen surface and is in principle accessible to a direct measurement, for example, by taking an image of the probe without any sample on a camera, if the imaging system allows for it.

Mapping charges and potentials

In summary, the measurement of the first moment $\langle \vec{p}_\perp(\vec{R}) \rangle$ in diffraction patterns can be directly related to the local electric field in thin specimen, whereas the intensity distribution of the STEM probe, determined by the size of the objective aperture, aberrations, as well as partial spatial and temporal coherence, limits the spatial resolution. In essence, one can hence define

$$\vec{E}_\perp^{P,m}(\vec{R}) = -\frac{v}{e} \cdot \langle \vec{p}_\perp(\vec{R}) \rangle \quad (20)$$

to be the *measured* projected electric field in Volts. By the laws of electrostatics, its divergence is proportional to the measured projected charge density in Cm^{-2} ,

$$q^{P,m}(\vec{R}) = \epsilon_0 \cdot \text{div} \vec{E}_\perp^{P,m}(\vec{R}) = -\frac{\epsilon_0 v}{e} \cdot \text{div} \langle \vec{p}_\perp(\vec{R}) \rangle, \quad (21)$$

which is shown in Fig. 5D for the WSe₂ experiment. Furthermore, the electrostatic electric field is the negative gradient of the electrostatic potential, $\vec{E} = -\vec{\nabla} \phi$. Inserting into Eq. (21), the measured projected electrostatic potential can thus be obtained by solving Poisson's equation

$$\Delta \phi^{P,m}(\vec{R}) = -\frac{1}{\epsilon_0} q^{P,m}(\vec{R}) \quad (22)$$

starting from a given charge density. For example, the integration can be performed by expressing the Laplacian as finite differences in an iterative five or nine-point stencil scheme, as was done to generate Fig. 5C.

Another option is to integrate the electric field directly, for which the most direct approach would be to calculate $\phi^{P,m}(\vec{R})$ from cumulative potential energy differences $\vec{E}_\perp^{P,m}(\vec{R}) \cdot \Delta \vec{R}$ with $\Delta \vec{R}$ connecting adjacent scan pixels. However, the presence of noise causes this integration scheme to be very unstable except for simulated data. An alternative consists of making use of the Fourier transform, where the gradient operator transforms into the multiplication with $\vec{Q}$, in analogy to the real- and Fourier space representations of the momentum operator in Eqs. (1) and (2), respectively. It is straight forward to show that

$$\phi^{P,m}(\vec{R}) = \mathcal{F}^{-1} \left\{ \frac{\vec{Q}}{2\pi i Q^2} \cdot \mathcal{F} \left[\vec{E}_\perp^{P,m} \right] (\vec{Q}) \right\} (\vec{R}) \quad (23)$$

provides the potential distribution except for the DC component $Q = 0$, essentially via scalar multiplication of the 2D Fourier transforms of the electric field components with $\vec{Q}/Q^2$, followed by an inverse Fourier transform of the result.

It is instructive to elucidate the differences between integrations based on Eqs. (22) and (23), respectively. Since the former starts from the second, the latter from the first derivative, different knowledge about the boundary conditions is needed. In particular,

Fig. 5 First moment-based electrical properties of a WSe₂ bilayer. An MR-STEM scan with 256×256 scan pixels taken with 200 keV electrons with a probe-corrected instrument equipped with a Medipix 3 camera. Each panel shows the respective quarter of the scan. (A) Momentum transfer $\langle \vec{p}_\perp(\vec{R}) \rangle$ from first moments in units of Planck's constant per nm, from Eq. (4). (B) Measured electric field, that is, $-\frac{V_z}{e} \langle \vec{p}_\perp(\vec{R}) \rangle$. (C) Measured electrostatic potential determined from the measured electric field. (D) Measured charge density.

solving Poisson's equation takes only those charges into account which lie inside the scanned region, whereas integrating the electric field directly includes the effects from charges outside, too. However, the Fourier integration in Eq. (23) imposes periodic boundary conditions. In any case, $\phi^{P,m}(\vec{R})$ can only be determined up to an additive constant.

Polarization and meso-scale electric fields

The physical properties of nanotechnological devices such as laser diodes or field effect transistors are often governed by electric fields that vary at length scales in the nanometer range. Important examples are pn junctions as well as spontaneous and piezoelectric fields in semiconductor optoelectronics which, by the quantum-confined Stark effect, have dramatic impact on the emission properties. Furthermore, controlling ferroelectric polarizations at the nanoscale gained rapid interest in the field of information technology. Consequently, the capability to quantify such meso-scale electric fields is a key component for understanding the structure-property-functionality relationships.

At first glance, electric field measurement at the meso-scale seems less complicated than dealing with subatomic fields as in Fig. 5 because the requirements for the spatial resolution appear less strict. However, any interaction of relativistic electrons with the specimen is determined by the full electrostatic potential built up by atomic and possible meso-scale components. At a second glance, the situation is hence much more complicated because atomic and meso-scale components need to be separated. In addition, both contributions have significantly different orders of magnitude. Atomic fields as measured in Fig. 5B are in the V/pm range assuming specimen thicknesses in the nm range. Contrary, typical polarization-induced electric fields are of the order 10 MV/cm, that is, approximately three orders of magnitude smaller.

On the one hand, rather thick specimens should thus be used to measure meso-scale fields so as to transfer sufficient momentum. On the other hand, Eq. (18) is only valid up to a thickness of a few atomic layers in matter, where atomic electric fields vary rapidly at the scale of the probe and distort it significantly (MacLaren et al., 2015; Müller-Caspary et al., 2017).

Nevertheless, the correlation in Eq. (18) can be replaced simply by $\vec{E}_P$ if $\vec{E}_P$ doesn't show lateral gradients at the scale of the intensity $|\psi(\vec{r})|^2$ in the specimen. This suggests to write $\vec{E}_P$ as the sum of a constant part $\vec{E}_{\text{ext}}$ and (atomic) contributions that vary at the scale of the interaction volume diameter and are affected by dynamical scattering. Then, the momentum transfer reads

$$\langle \vec{p}_\perp(\vec{R}) \rangle = -\frac{e}{v} \cdot \vec{E}_{\text{ext}} \cdot t + \langle \vec{p}_\perp(\vec{R}) \rangle_{\text{dyn}}, \quad (24)$$

where t is the specimen thickness.

One approach to solve for $\vec{E}_{\text{ext}}$ makes use of symmetry considerations in crystals. For a single scan point $\vec{R}$, the dynamic part $\langle \vec{p}_\perp(\vec{R}) \rangle_{\text{dyn}}$ is intuitively unpredictable when the specimen thickness is large. For example, a complex vector field $\langle \vec{p}_\perp(\vec{R}) \rangle$ can result where atomic sites are no more sinks of momentum transfer, as illustrated schematically in Fig. 6A. Assuming the presence of an

Fig. 6 Unit cell averaging concept for meso-scale electric field measurement. (A) Due to dynamical scattering, the momentum transfer distribution across a unit cell can be counter-intuitive, but is symmetric in centrosymmetric geometries. The unit cell average of atomic-scale contributions thus vanishes such that (B) a superimposed constant external field (exaggerated) remains as a residual. (C) Systematic error $\vec{\delta}$ for w-GaN is obtained by multislice assuming $[11\bar{2}0]$ zone axis and 300 keV electron energy. The unit cell (UC) average of the momentum transfer along the nonpolar direction vanishes; hence $\delta_{1\bar{1}00} = 0$ (red) opposite to δ_{0001} measured along the polar direction. The broken symmetry is sketched in the insets. A constant electric field of 5 MV/cm causes the momentum transfer shown in blue.

inversion center for the moment, any scan point has nevertheless a counterpart in the unit cell with a momentum transfer having the opposite sign. In other words, the unit cell average of $\langle \vec{p}_\perp(\vec{R}) \rangle_{\text{dyn}}$ must vanish in respective structures. Consequently, averaging $\langle \vec{p}_\perp(\vec{R}) \rangle$ in Eq. (24) over all scan points in a unit cell delivers $\vec{E}_{\text{ext}}$ according to Fig. 6B, assuming that the usually tiny amount of mistilt introduced by the constant component has negligible effects on the dynamical scattering.

Unfortunately, polarization effects emerge as a consequence of symmetry breaking, for example, in ferro- and piezoelectric materials and materials with spontaneous polarization. In addition to the desired dependence on $\vec{E}_{\text{ext}}$, the unit cell average of $\langle \vec{p}_\perp(\vec{R}) \rangle$ can involve a systematic error $\vec{\delta}$ arising from the fact that averaging $\langle \vec{p}_\perp(\vec{R}) \rangle_{\text{dyn}}$ is finite, and we find

$$\left[\langle \vec{p}_\perp(\vec{R}) \rangle \right]_{\text{UC}} = -\frac{e}{v} \cdot \vec{E}_{\text{ext}} t + \vec{\delta}(t), \quad (25)$$

where $[\dots]_{\text{UC}}$ denotes the unit cell average. The measurement of polarization-induced electric fields thus involves the estimation of $\vec{\delta}$, which is usually done via multislice simulations (Müller-Caspary et al., 2019; Strauch et al., 2023).

As an example, Fig. 6C shows $\delta_{1\bar{1}00}$ (red) and δ_{0001} (black) thickness-dependent for wurtzite-type GaN. Since the $[1\bar{1}00]$ direction is nonpolar, this component vanishes in the unit cell average for symmetry reasons despite strong dynamical scattering, as sketched in the left inset. On the contrary, δ_{0001} takes finite values of more than $1 \frac{h}{\text{nm}}$ due to the polarity generated by the Ga-N dumbbells, as illustrated on the right. Despite that, the blue curve shows that a superimposed polarization-induced electric field $\vec{E}_{\text{ext}}$ of a few MV/cm dominates the momentum transfer from a specimen thickness of a few tens of nanometers on and can hence be measured (Müller-Caspary et al., 2019).

Angle-resolved STEM

Methodology

Another prominent technique that allows for the condensation of the four-dimensional MR-STEM datasets into a more concise form while still preserving critical information is AR-STEM. Here, the MR-STEM data are azimuthally averaged in momentum space, yielding a radial intensity distribution

$$I_{\text{rad}}(q_\perp, \vec{R}) = \frac{1}{2\pi} \int I(q_\perp \cos \varphi, q_\perp \sin \varphi, \vec{R}) d\varphi. \quad (26)$$

It is also common practice to use the scattering angle $\vartheta = \lambda q_\perp$ rather than the spatial frequency modulus $q_\perp$.

Similarly to how FM-STEM can be seen as a progression of DPC-STEM, AR-STEM is an evolution of the traditional STEM ring detectors. It formally increases the number of rings to the continuous limit, even though in practice only a discrete sampling of the diffraction pattern is achievable, as discussed above.

Combining MR-STEM with AR-STEM is a natural fit, as the integral in Eq. (26) can be translated into a discrete sum

$$I_{\text{rad}}(q_{\perp}, \vec{R}) \approx \frac{1}{n_{q_{\perp}}} \sum_{q'_{\perp} \approx q_{\perp}} I(\vec{q}'_{\perp}, \vec{R}), \quad (27)$$

where $n_{q_{\perp}}$ is the number of pixels summed up for a certain $q_{\perp}$. The criterion which pixels $q'_{\perp}$ are to be summed for a given $q_{\perp}$, denoted slightly informal here by $q_{\perp} \approx q'_{\perp}$, is chosen depending on the resolution and signal-to-noise ratio of the MR-STEM dataset, and the desired sampling of the scattering angle.

This sum results in a three-dimensional dataset that retains the two-dimensional spatial resolution of the MR-STEM scan and allows for the analysis of specific scattering angle ranges. The angular multirange analysis enables the determination of specimen properties such as chemical composition and homogeneity, or geometrical thickness by comparison to simulated reference data (Müller-Caspary et al., 2016; Grieb et al., 2021). The multitude of angle ranges that can be chosen *a posteriori* from a sufficiently sampled I_{rad} enables the simultaneous measurement of several specimen properties while at the same time artifacts from, for example, inhomogeneous detector sensitivity or diffraction pattern distortion can be avoided or reduced (Krause et al., 2016). This puts it a clear advantage over conventional STEM with a single or at least only few detectors.

For completeness, further AR-STEM capable setups are to be mentioned. One example is the positioning of an iris aperture in front of a conventional circular or annular detector, which allows to acquire different angle ranges by choosing the iris opening (Müller-Caspary et al., 2016; Grieb et al., 2021). The characteristic of this concept is the inherent rotational averaging during the acquisition. In that case, the azimuthal information is not recorded so that information is only available in dependence of the momentum modulus. However, acquisition speeds in the MHz range can be reached using established ring detectors which are much higher compared to common kHz frame rates in frame-based MR-STEM experiments.

Applications

Fig. 7 illustrates the possibilities of AR-STEM for quantitative evaluation: Multislice simulations of Ga(NAs) with varied specimen thickness and nitrogen concentration predict a scattering angle range from 42 to 66 mrad, in which the radial intensity is very sensitive to a change of the nitrogen content, and another interval between 82 and 141 mrad, in which the intensity is nearly independent of the composition but only depends on the specimen thickness. Hence, these two intervals can be used for the simultaneous evaluation of both specimen thickness and nitrogen concentration in a dedicated AR-STEM experiment.

The experimental results of this concept are shown in Fig. 8. From the radial AR-STEM intensity $I_{\text{rad}}(\theta)$, the intensities in these two intervals are calculated by integration. A subsequent comparison to the simulated reference data yields the quantitative composition and thickness with atomic resolution, clearly revealing a nitrogen-rich layer. While this specific evaluation could, in theory, also be executed with two dedicated conventional ring detectors of appropriate geometry, AR-STEM has the significant advantage that the choice of the angle interval can be made and changed after the measurement, possibly on the basis of observations made in it.

An example for such an adaptive evaluation is given in Fig. 9: A GaN/InGaN layer was investigated with AR-STEM. In this material system, it is common to observe intensity alterations near the layer interfaces. The cause of these are strain effects due to the different covalent radii of In and Ga. However, their inclusion into reference simulations is tedious and an evaluation with atomic resolution is impossible without substantial additional effort. Here, the AR-STEM images immediately reveal that there is a scattering angle range near 36 mrad in which the effect nearly vanishes. Using this interval, therefore, enables a much easier and quicker evaluation.

Fig. 7 Simulated AR-STEM intensity for GaNAs: The plot shows two radial intensity curves for pure GaAs of 100 and 200nm thickness, respectively, and another for 200-nm thick GaN_{3%}As_{97%}. In the higher angle range B, the nitrogen concentration has very little influence on the intensity, which is primarily determined by the thickness. For lower angles, however, the N concentration causes the massive difference marked in red. This gives the interval A a high sensitivity for the composition (Müller-Caspary et al., 2016).

Fig. 8 An exemplary quantitative evaluation of an AR-STEM measurement: (A) and (B) show the integrated intensity images of a GaAs/GaNAs nanostructure from the two intervals marked in Fig. 7, recorded using an iris aperture-based AR-STEM setup. By comparison to the simulated reference data, both N concentration (C) and specimen thickness (D) are determined (Müller-Caspary et al., 2016).

Fig. 9 AR-STEM image of a GaN/InGaN nanostructure: Small and large scattering angles ϑ show intensity variations in areas of pure GaN next to the layer in the center (red arrows). These are caused by strain effects due to the larger lattice constant in the layer complicating quantitative evaluation. For scattering angles around 36mrad, the effect disappears (green arrow). The given angles mark the center of the respective angle intervals used to form the images (Grieb et al., 2022).

Impact of inelastic scattering

The different evaluation schemes for MR-STEM data sets introduced above were primarily discussed in the context of elastic electron-sample interactions, where the specimen is completely represented simply by an electrostatic potential. In practice, however, electrons that have undergone inelastic interactions, that is, exchanged energy with the specimen, make up a significant fraction of the detected signal. In many cases they are even in the majority. The predominant inelastic interactions are related to energy transfer to phonons, that is, collective oscillations of the crystal lattice, and plasmons, that is, oscillations of the electron gas.

Fortunately, the inclusion of these two scattering mechanisms into the formalism used in the previous sections is possible. For phonons, this can be done through the so-called *frozen phonon* (FP) formalism. In brief, this means that instead of using one electrostatic specimen potential, where atoms are assumed to reside on their ideal positions, the calculations are done for multiple potentials, where the atoms have been displaced according to the thermodynamic probability distribution. The resulting images and signals including phonon scattering are then found by averaging over all these different displacement configurations. Going into detail here is beyond the scope of this article, but the interested reader is referred to Wang (1998), Van Dyck (2009), Krause et al. (2018), and Forbes et al. (2010).

The inclusion of plasmons is generally more complicated and more computationally demanding. However, to assess its influence on MR-STEM and subsequent evaluations, it can be shown that the effect of plasmon scattering on each diffraction pattern can in very good approximation be modeled by a convolution ($\otimes$)

$$I_{\text{plasmon}}(\vec{q}_{\perp}) \propto I_{\text{elast.}}(\vec{q}_{\perp}) \otimes \sqrt{\frac{1}{q_{\perp}^2 + q_{\text{plasmon}}^2}}. \quad (28)$$

The quantity q_{plasmon} is the modulus of a characteristic plasmon scattering wave vector that is typically much smaller than the reciprocal lattice vectors of a crystal. Whereas there is a lot to account for in detail, it can be instantly seen that the elastic intensity is convolved with a sharp and rotationally symmetric function. For more details, [Beyer et al. \(2020\)](#), [Robert et al. \(2022\)](#), and [Verbeeck et al. \(2005\)](#) are recommended.

In the light of these descriptions, it can be concluded that the influence of inelastic scattering on FM-STEM is rather small and oftentimes negligible: As the convolution of an arbitrary diffraction pattern with any rotationally symmetric function will preserve the original COM, there will be no effect of inelastic scattering as long as these models hold true. Even if asymmetric contributions are taken into account, they are generally much smaller and their effect is hence still not significant.

For AR-STEM, the situation is very different: The approximately rotationally symmetric inelastic scattering redistributes intensity from the bright field center (low scattering angles) toward the outer rim of the diffraction pattern (high scattering angles). The radial intensity is therefore altered critically. Especially phonon scattering makes up the major part of scattering into high angles and cannot be neglected. Fortunately the FP methodology outlined above allows for a relatively straightforward inclusion in reference simulations.

The inclusion of plasmons into quantitative AR-STEM simulations is much more challenging. While Eq. (28) can be applied, the knowledge of several constants is critical for its quantitative application, especially the total plasmon scattering cross-section and the exact plasmon dispersion relation. Although these values are tabulated for common materials, they are often not known precisely enough to achieve full quantitative agreement between simulation and experiment.

Nevertheless, plasmon scattering can have a grave influence: Especially for smaller scattering angles, neglecting them can lead to a significant underestimation—in some cases by a factor of up to 2 ([Müller-Caspary et al., 2016](#); [Beyer et al., 2020](#)). If, therefore, an accurate simulation including plasmons cannot be realized, this angle range has to be avoided for quantitative evaluations. The maximum scattering angle that is impacted significantly by plasmons is dependent on specimen material and orientation. However, as a rule of thumb, scattering angles less than 25 mrad above the convergence angle should be avoided. In fact, this is the reason why interval A in [Fig. 7](#) was chosen as shown there, even though smaller angles seem to promise an even better sensitivity to the nitrogen concentration.

Conclusion

In MR-STEM, a detailed diffraction pattern is recorded in dependence of the position of a scanning electron probe. This enables a high degree of flexibility in that virtual detectors can be defined after the acquisition in software and are not given by a rigid a-priori detector setup anymore. Besides traditional imaging schemes that produce conventional TEM, thickness- and Z-contrast now with dedicated, optimized disk- and ring detector geometries, MR-STEM enables completely new imaging modes.

A prominent method is FM-STEM, which yields the average lateral momentum (transfer) of the electron wave after the interaction with the specimen by assigning the COM of each diffraction pattern to the respective scan coordinate. This vector field can be directly related to the electric field under certain conditions. If the specimen is thin enough that one can assume that the intensity distribution of the probe is preserved, the momentum transfer is proportional to the correlation between electric field and probe intensity. Usually this approximation is valid for 2D materials only, or specimen with a thickness of a few nanometers. The unit cell average of the momentum transfer can be used as a measure of an external, for example, polarization-induced electric field, whereas systematic errors arising from a broken inversion symmetry need to be assessed in simulations.

In AR-STEM, azimuthal averaging in diffraction patterns condenses the MR-STEM dataset to its radial scattering information. Because specific specimen properties can leave fingerprints in characteristic scattering angles, this can either allow for the simultaneous measurement of a multitude of specimen properties by an angular multirange analysis, or it can help to avoid unwanted contrast mechanisms such as lattice deformations or contamination. With the nearly complete registration of scattering, MR-STEM necessitates a careful look at inelastic effects such as plasmon excitations, especially at small scattering angles.

Prospects

The multidimensional concept of MR-STEM puts high demands on the data acquisition speed and the computational performance to evaluate four-dimensional datasets, both to be improved for efficient and versatile in situ data evaluation. On the technological side, even faster cameras with MHz rate read-out would be desirable to achieve established STEM acquisition speeds. Due to the limited dose, MR-STEM datasets become rather sparse then, such that single-event-based recording and processing schemes seem to pave a promising way. Methodologically, electric field mapping at atomic and meso-scale has still large unlocked potential to be explored since the most interesting applications in solid-state physics require precisions and accuracies that allow for the detection of bonding effects and polarization-induced electric fields in a robust manner. In addition, the role of inelastic scattering, primarily due to plasmons, appears critical for a quantitative understanding of the whole MR-STEM dataset. Recording MR-STEM data energy-dependent or even energy-resolved, and developing efficient simulation schemes for inelastic scattering provide promising future directions, and surely one of the biggest challenges in this field.

Acknowledgments

We thank our colleagues Dr. Benjamin März and Dr. Tim Grieb for providing experimental data, and Max-Leo Leidl for his professional typographical support. The authors thank Andreas Rosenauer, Josef Zweck, Sandra Van Aert, and Johan Verbeeck for the scientific creativity and inspiration in their groups as a catalyst for the MR-STEM development during the past decade.

Abstract

Confocal [optical sectioning microscopy](#) is a direct visualization method using fluorescent labels that is increasingly applied in [condensed matter physics](#) to study the structure and dynamics of complex fluids. The technique, developed for imaging cells and thick biological tissues, is borrowed from the life sciences. The focus of this article is the theory and practice of [confocal microscopy](#) in materials science. The instruments used to optically section through samples are described, together with their advantages and limitations. Auxiliary methods, such as fluorescent [particle synthesis](#) and quantitative image processing, are also summarized. Finally, current applications of confocal optical microscopy in condensed matter physics are discussed.

Key points

- Understand why fluorescently-stained specimens form blurred images
- Learn why optical sectioning is required
- Understand how optical sectioning is performed
- Learn about the different types of confocal microscopes

Introduction

Standard [optical microscopy](#) techniques, including microscopy by bright field and epifluorescence illumination, fail for the optically dense specimens that are typical of applications in materials science and [condensed matter physics](#).

The origin of the [optical density](#) is often a combination of scattering due to strong [refractive index](#) contrast, emission due to high [fluorophore](#) density, or attenuation due to the long [optical path](#) of an object plane located deep in the specimen. This problem was first encountered and addressed in the life sciences. There, methods were sought to image deep into cellular tissue without the need for laborious sectioning. While sectioning is laborious, it also precludes examination of living tissues. More importantly fluorescent labels are *self-luminous*: the fluorescently-labeled specimen emits signal throughout its entire volume, which often exceeds the depth of field of the microscope objective (the depth of field is the axial depth of the space on both sides of the object plane within which the object can be moved without detectable loss of sharpness in the image, and within which features of the object appear acceptably sharp in the image while the position of the image plane is maintained). The consequence is the out-of-focus fluorescent signal emitted by the specimen blurs those in-focus details in the image.

Principle of confocal optical microscopy

Optical sectioning is achieved by point illumination and point detection. By restricting the illumination to a pinhole, rather than illuminating the entire field of view at once, as in widefield microscopy, it becomes possible to build up a blur-free image in three

[☆]*Change History:* November 2022. J Sanderson updated the chapter.

Fig. 1 A depletion gel of fluorescent poly(methyl methacrylate) colloids $\sim 1.9\ \mu\text{m}$ in diameter dispersed in a refractive index and density-matched solvent imaged with a 1.4 NA objective by (a) confocal fluorescence and (b) epifluorescence microscopy. The comparison demonstrates the image-forming capability of confocal microscopy for the optically dense specimens that are characteristic of condensed matter physics and materials science.

dimensions. The detection pinhole rejects light not originating from the vicinity of the object plane. The entire image is built up point-by-point in each frame, as the diffraction-limited spot of the illuminating beam rasters across the frame or the stage is moved, rather like reading words in lines along a page of script in a book.

The term “confocal” is a portmanteau of the words “conjugate focus” since the projection of the illumination pinhole, the plane of focus within the specimen and the back-projection of the detector pinhole are all situated at conjugate focal planes.

When the confocal detection scheme is combined with the capability to move the object plane through the specimen, to create so-called “z-stacks,” a powerful technique for the imaging of three-dimensional (3D) volumes is made possible.

While fluorescence imaging is the most common application of confocal microscopy, visualization of structure by scattered or reflected light is also feasible. Fig. 1 shows the difference in image forming capability for a gelled colloidal suspension (volume fraction of 10%) imaged by confocal and epifluorescence microscopy.

The direct visualization of image volumes by confocal microscopy has been applied in many areas of condensed matter physics. In experimental statistical mechanics, application of quantitative image processing to 3D intensity maps generated by confocal microscopy has been used to quantify the thermodynamic and structural properties of glasses and gels comprised of colloidal particles. The field-induced and template-induced crystallization of novel colloidal phases has been observed and quantified. The 3D structure of mesoporous phases has been discovered. The diffusivity of fluorescent probes in polymer networks has been quantified. Particle tracking routines applied to time series of confocal image volumes have observed cooperative motion in colloidal suspensions. These observations can be used to understand the fundamental origins of glass transition.

These applications require understanding of the spatial and temporal resolution of confocal microscopy, the use of image processing tools to quantify acquired image volumes, and synthesis of model materials suitable for confocal imaging. These issues are discussed in subsequent sections. First, the configurations commonly used in confocal microscopy are described.

Confocal laser scanning microscopy

The conceptual idea of rejecting out-of-focus emission from the detector by adding an aperture (usually referred to as the “pinhole”) to the detection system has been implemented in two principal ways. Fig. 2a shows the single-beam raster-scanning confocal laser scanning microscope (CLSM).

The confocal aperture is adjusted to optimize the trade-off between axial resolution and optical section thickness inherent to confocal microscopy. In the CLSM configuration, the image is collected pointwise with a single detector, usually a photodiode or photomultiplier tube. A PMT is used because these enhance the weak signal and can also very rapidly collect single points of light emitted as signal. Using an sCMOS or CCD detector would be far too slow.

In order to ensure sufficient emission from the excitation focal point in the objective plane, laser illumination is used. Scanning mirrors manipulate the path of an expanded, spatially filtered source so that the illuminated point is rastered across the object plane. The speed of the galvanometrically-actuated scanning mirrors determines the acquisition rate of a 2D image. At current capabilities a line scan can be executed at rates up to $\sim 1\ \text{kHz}$. Thus, a 512×512 pixel scan can be acquired in less than one second. 3D image volumes are acquired by piezoelectric actuation of the specimen relative to the objective. This actuation can be conducted with nanoscale resolution and micrometer-scale repeatability. A $1024 \times 1024 \times 200$ 3D scan, a typical dataset, requires a few minutes with a good CLSM.

Fig. 2 Schematics of the: (a) confocal laser scanning microscope and (b) Nipkow spinning disc confocal microscope.

The **confocal imaging** system is used in conjunction with the components of a standard **optical microscope**. In particular, the microscope objectives and **specimen preparation** for CLSM and **optical microscopy** are identical. Just as in widefield epifluorescence technique, in CLSM the excitation and emission illumination traverse the microscope objective in reverse directions. Typically, a dichromatic **beam splitter** ensures that only emission from the specimen passes to the detector optics. Alternatively, an acousto-optic beam splitter (AOBS) provides flexibility in selecting transmission bands. The CLSM is commonly used in non-confocal fluorescence mode to first locate and focus the specimen. Switching to laser-scanning confocal mode, the detection system must then separate the **emission spectrum** into bands corresponding to the wavelength ranges relevant to the multiple fluorophores. This decomposition can be accomplished with a cascade of dichroic filters. Alternatively, after the confocal **pinhole**, the emission can be spectrally resolved with a prism and adjustably filtered with mechanical slits before detection with a photomultiplier tube. While fluorescence visualization is a frequent application of CLSM, some situations require analysis of reflected or scattered light. This method, called reflection CLSM, is of particular interest for measurements of topography in materials science and solid-state electronics.

Variations on the design of Fig. 2a include substitution of the confocal pinhole for a confocal slit. This configuration allows faster scanning with reduced resolution.

Nipkow spinning disc confocal microscopy

The **pointwise** scanning of CLSM imposes a significant limitation upon the image acquisition speed of this method. The Nipkow spinning disc **confocal microscope**, now more often called the spinning disc microscope, shown in Fig. 2b, is an alternate method that can achieve video rate imaging. Current configurations use two synchronized **discs rotating** at a rate that scans the image at 360 frames s^{-1} . One disc is patterned with an array of many thousands of **pinholes**. The pinhole diameter is optimized for high **numerical aperture** (NA) objectives (optimization for NA = 1.4 is typical). The excitation illumination is chopped by the pinhole array. A second rotating disc, located prior to the pinhole disc, consists of a **microlens array**. Each microlens focuses **excitation light** onto a corresponding pinhole, thereby significantly increasing the excitation intensity supplied to the specimen. The pinhole spacing relative to its diameter is optimized to reduce collection of the emission signal from one pinhole by a neighboring one. Thus, the pinhole disc has inherently low transmission efficiency without incorporation of the microlens array.

Because the primary excitation is subdivided into a number of sources by the pinhole disc, multiple points of the objective plane are simultaneously interrogated. Emission from the specimen propagates through the rotating pinhole array in the reverse sense. In this case, each pinhole serves as the confocal aperture. The emission paths are diverted to the detection system by a dichroic **beamsplitter**. A sCMOS or CCD array images the emission paths in widefield mode. The read-out rate of the digital camera detector is currently the limiting step in the time required to acquire a 2D image. 3D image volumes are acquired by relative **actuation** of specimen and objective, just as for CLSM.

At full frame resolution, image acquisition rates for spinning disc **confocal microscopy** are at least an order of magnitude faster than CLSM. However, because the primary incident laser source is subdivided into a number of beams, the excitation supplied to a particular point in the object plane is typically less than CLSM. In addition, the confocal aperture is not adjustable as is the case in the CLSM.

Limits of optical resolution

Confocal microscopy presents unique opportunities for 3D imaging of microstructure; however, the method is an optical one and thus resolution limits are dictated by the wavelength of light. Here, two limits of optical resolution are considered. The first, resolution in the object plane (lateral optical resolution), is governed by the Rayleigh resolution criterion. The second, resolution perpendicular to the object plane (axial optical resolution or optical section thickness), is dictated by the point spread function. The effect of confocal aperture diameter on resolution is also assessed.

According to the Rayleigh criterion, the resolution limit occurs when the central maximum of the Airy pattern of one point emitter is directly overlapping with the first minimum of the Airy pattern of the adjacent point emitter. In other words, the minimum resolvable separation between the points is the radius of the Airy disc. For unpolarized light, this lateral optical resolution is $0.61\lambda/\text{NA}$ where λ is the wavelength of light and NA is the numerical aperture of the objective. For $\text{NA} = 1.4$, lateral resolution is $\sim 0.2\ \mu\text{m}$ and this is the best resolution currently possible for optical microscopy. The Rayleigh criterion is a useful estimate of lateral resolution in both widefield and confocal microscopy.

In confocal microscopy, the criterion for axial object resolution commonly adopted is that two points oriented perpendicular to the object plane can be resolved if the first minima in their point spread functions (evaluated along the optical axis) are distinct. This criterion has the same physical basis as the one for the Rayleigh resolution and leads to a characteristic axial optical resolution of $2\lambda/(\text{NA})^2$. For $\text{NA} = 1.4$, axial resolution is $\sim 0.5\ \mu\text{m}$, slightly greater than twice the lateral object resolution.

These resolution criteria are the best achievable. Actual microscopes achieve lower resolution due to polarization effects and nonidealities. For example, the confocal aperture diameter has a profound effect on optical section thickness. In scanning devices, this fixed diameter is adjusted to optimize the trade-off between image intensity and axial resolution. Units scaled on characteristics of the diffraction point spread function are a convenient basis to specify the aperture diameter and its performance. The dimensionless lateral scale in the image plane is then $(2\pi/\lambda)(\text{NA}/M)r_a$, where M is the magnification in the image plane and r_a is a particular image plane dimension such as the aperture radius.

Calculations and experiments for confocal visualization show that the optimal confocal section thickness is attained with a confocal aperture dimension that corresponds to one Airy diffraction disc (cf. dimensional scaling above). Aperture reduction below this value yields only small improvement in resolution at the expense of reduced image intensity. As the confocal aperture is opened, progressively greater amounts of out-of-focus emission are admitted to the detector; however, resolution deteriorates. One way in which this effect has been quantified is by imaging a plane reflective coating. In this experiment, the full-width at half maximum (FWHM) of the axial intensity, a practical measure of the optical thickness and axial resolving power, doubles as the aperture is increased from one Airy disc to two. Fig. 3 displays images that show the qualitative effect of confocal aperture on image intensity and resolution as the aperture is opened for a colloidal crystal of interest to soft condensed matter physics and materials science.

The resolving power of a confocal microscope is marginally improved over that of a widefield microscope because the overall image PSF is the product of both illumination and detection PSFs. Therefore resolving power is improved by closing down the pinhole, but at the expense of rejecting most of the emitted signal. By collecting the rejected light with a high-sensitivity multi-channel detector, the emitted signal can be processed to improve the signal-to-noise ratio and resolving power in the image. This technique is called “pixel reassignment,” and is of increasing importance in the life sciences.

Fig. 3 The effect of pinhole aperture on the image-forming capability of confocal laser scanning microscopy. In optical units nondimensionalized on the size of the Airy diffraction disc, the images are for confocal apertures of 0.5, 1.0, and 2.0 (from left to right). The specimen is a colloidal crystal of colloidal poly(methyl methacrylate), diameter $\sim 1.9\ \mu\text{m}$, in a refractive index and density-matched solvent for which electrostatic interactions between the colloids have been screened by the addition of an organic salt.

Model materials for confocal imaging

Most applications of [confocal microscopy](#) in [condensed matter physics](#) have used fluorescent imaging. The need to incorporate [fluorophores](#) into structures to be imaged imposes a constraint on materials that can be studied. Thus, studies of experimental [statistical mechanics](#) and self-assembly using [colloidal models](#) require methods for syntheses of monodisperse [colloidal particles](#). Determination of bulk behavior requires imaging deep within the sample, where effects of the sample boundary are minimized. To accomplish such imaging, the particle and suspending medium must be at least approximately [refractive index](#) matched; otherwise scattering reduces the intensity and image-forming quality of the emitted signal returned to the detector.

A common approach to this challenge is to synthesize monodisperse colloids to which an oligomeric stabilizing layer is grafted to the particle surface. This steric layer ensures colloid stability in mixtures of [organic solvents](#) that match the refractive index of the colloid. A number of strategies exist to incorporate fluorescent dyes into silica or poly(methyl methacrylate) colloids during [particle syntheses](#). For polymer colloids, the post-synthesis method of colloid swelling and dye absorption is also possible; however, these processes change the potential interactions between the colloids in ways that are poorly understood.

In addition to refractive index matching, solvent mixtures are often selected to match the density of particle and solvent so as to minimize colloid sedimentation (or flotation). Such particle motion, even when small, can destroy fragile gel or crystalline structures that arise due to the physical interactions between particles. Sedimentation also interferes with the study of Brownian and cooperative particle motion by particle tracking.

Long duration kinetic and dynamic studies require fluorescent dyes that are resistant to photobleaching. In the life sciences, the limitation of cytotoxicity on dye concentration means that photobleaching is an important factor in dye selection. While the situation is less severe in condensed matter physics (because [cytotoxic](#) effects are absent), recent work has favored more photostable dyes, such as Alexa Fluor, DyLight, Cy dyes—to name a few—over traditional ones such as fluorescein and [rhodamine](#).

Quantitative image processing for confocal microscopy

The 3D map of fluorescent intensity provided by [confocal microscopy](#) is a powerful qualitative indicator of complex fluid behavior. An even more fruitful approach is to use image processing to extract quantitative measures of structure and dynamics from the fluorescence maps. In 2D microscopy, a number of approaches for the interrogation of particle locations using edge detection and thresholding have been developed. Alternatively, particles can be identified from local intensity maxima and their locations then refined to [subpixel](#) resolution according to the distribution of brightness in the vicinity of the maxima. This latter approach, although computationally intensive, is readily extendable to the 3D particle location problem and has thus found wide application in confocal microscopy of colloidal systems. While estimates of the errors in particle location for these routines vary widely, the most significant [determinant](#) of the precision and accuracy of particle location is the delocalizing effect of Brownian motion on the timescale of image volume acquisition. For time series acquired at a rate such that the typical particle displacement is much less than the mean separation between particles, algorithms have been developed that reliably link particle locations in each frame into trajectories. The [trajectory analysis](#) yields dynamic information about Brownian and cooperative motion of the particles.

Once particle [centroids](#) and trajectories have been located, the information contained in the confocal image volumes is transformed into output of the same format that would result from a computer simulation of a corresponding model system. (In a typical image volume of $40 \times 40 \times 20 \mu\text{m}^3$ resolved by a high-resolution objective, the number of micrometer-sized particles is of order 10^4 . This number is not too different from the state-of-the-art computer simulation.) Thus, all the tools of [statistical mechanics](#) developed for the analysis of molecular, Brownian, and Stokesian dynamics simulations can be applied to the experimental results. This formal correspondence between experiment and simulation offers an unusually rich avenue for direct comparison between the two. [Fig. 4](#) displays the results of quantitative image processing of a depletion colloidal gel comprised of monodisperse fluorescent poly(methyl methacrylate) colloids of diameter $\sim 1.9 \mu\text{m}$. The projections of the confocal image volume in two orthogonal planes qualitatively demonstrate the degree to which [image processing methods](#) locate the imaged particles.

Applications in condensed matter physics

The qualitative fluorescence imaging and 3D sectioning capability of [confocal microscopy](#) have found wide application in the qualitative characterization of microstructure in [colloidal suspensions](#), [polymer gels](#), immiscible blends, and composites. Recently, the additional step of generating quantitative measures of complex fluid structure and dynamics from confocal microscopy has been taken. In this brief summary, the focus is on these new developments. These advances have been driven by three recent steps forward: (1) methods to synthesize monodisperse fluorescent [colloidal particles](#) have been discovered; (2) confocal microscopy, borrowed from the life sciences, has been applied to image materials comprised of colloidal particles; (3) techniques of quantitative image processing have been developed to extract the locations and trajectories of the colloidal particles.

Confocal microscopy has been used to interrogate the phase behavior of concentrated colloidal suspensions interacting through screened [electrostatic forces](#). The self-assembly of colloidal particles into ordered crystals is a step in one method to produce [photonic](#) materials. The effect of an [applied electric field](#) on colloidal crystal structure has also been discovered. The nucleation and growth of crystal nuclei in colloidal suspensions has been directly visualized. The particle correlation function and coordination

Fig. 4 Illustration of methods for quantitative image processing. Image (a) is a representative 2D slice from a 3D image volume of a depletion gel of poly(methyl methacrylate) colloids (volume fraction of 10%, diameter 1.9 μm) imaged by CLSM. Image (b) shows a projection of ~ 20 2D lateral slices with an overlay of particle locations found within that volume by quantitative image processing. Image (c) shows a similar projection, but now in a plane that includes the **axial direction** of the microscope. Note that the optical resolution in the axial direction is reduced relative to the **lateral direction** because of the different characteristics of the 3D **point spread function** along the **optical axis** and in the objective plane.

number of hard-sphere glasses have also been quantified by direct visualization with confocal microscopy. Short-range attractive forces, included by conformational changes of grafted steric layers or by the depletion interactions induced by nonadsorbing polymer, lead to the assembly of amorphous gel structures. The clusters and voids that comprise these structures have been directly visualized with CLSM. Cooperative particle dynamics in the vicinity of the colloidal hard-sphere glass transition have been visualized by time-resolved confocal microscopy. The **thermal fluctuations** of gel backbone segments have likewise been quantified as have the flow-induced structures of colloidal gels as they are subjected to shear and compressional flow. These direct visualization studies of structure and dynamics in colloidal systems by confocal **optical microscopy** represent a new and fruitful approach to understand the behaviors of complex fluids that are of broad interest in soft **condensed matter physics** and materials science.

Conclusion

Confocal **optical sectioning microscopy** is a direct visualization method of viewing detail in thick fluorescent specimens that would otherwise form blurred images.

Fluorescent labels are *self-luminous*: the fluorescently-labeled specimen emits signal throughout its entire volume, which often exceeds the depth of field of the microscope objective. The consequence is the out-of-focus fluorescent signal emitted by the specimen blurs those in-focus details in the image.

Optical sectioning is so-called because point illumination and point-detection are used to “slice” the sample with light to image deep into cellular tissue without the need for laborious mechanical sectioning. An aperture (usually referred to as the “pinhole”) in the detection system prevents the out-of-focus signal from being collected. The confocal aperture is adjusted to optimize the **trade-off** between **axial resolution** and optical section thickness inherent to **confocal microscopy**.

The **pointwise** scanning of CLSM imposes a significant limitation on the image acquisition speed of this method. The Nipkow spinning disc **confocal microscope**, now more often called the spinning disc microscope, is an alternative method that can achieve video rate imaging.

The Rayleigh criterion is a useful estimate of lateral resolution in both widefield and confocal microscopy. The resolving power of a confocal microscope is marginally improved over that of a widefield microscope because the overall image PSF is the product of both illumination and detection PSFs. Resolving power is improved by closing down the pinhole, but at the expense of rejecting most of the emitted signal. By collecting the rejected light with a high-sensitivity multi-channel detector, the emitted signal can be processed to improve the signal-to-noise ratio and resolving power in the image. This technique is called “pixel reassignment.”

Abstract

This article covers the observation of cyclotron resonance in a wide range of materials and systems that may be loosely defined as metals; they possess Fermi surfaces. While all involve magnetic fields and (mostly) cryogenics, details of the experimental techniques used are dictated by the carrier densities and skin depths of these “metals,” and range from simple transmission to complicated resonant cavities. A primary focus of this article is the extraction of the carrier scattering rate from cyclotron resonance, and various methods to recover the desired information from the raw data are described. The scattering rates thus deduced provide the purest gauge of the Landau-level width, and can be used to show how it is affected by various types of carrier scattering. Other techniques yield different values for the scattering rate, and the reasons for this are discussed. Finally, I describe the influence of many-body effects on the cyclotron-resonance lineshape and the effective mass measured, and give a brief summary of techniques related to cyclotron resonance.

Key points

- To introduce Landau quantization and cyclotron resonance.
- To explain the materials and systems—ranging from graphene and semiconductor heterostructures to elements, with cuprates, organic metals etc. in between—that are classified as “metals” and studied using cyclotron resonance.
- To describe the types of apparatus used to observe cyclotron resonance in these “metals,” and how the apparatus is chosen based on their carrier densities.
- To describe how quasiparticle scattering rates may be extracted reliably from the various cyclotron resonance experiments.
- To show why the quasiparticle scattering rates measured using cyclotron resonance differ from those deduced using other techniques.
- To give a brief description of the effective mass measured in cyclotron resonance, and how it is affected by many-body effects.
- To give brief descriptions of other phenomena related to cyclotron resonance.

Introduction

Landau quantization may occur when electrons in a solid are subjected to a magnetic field (Ashcroft and Mermin, 1976; Singleton, 2001). The excitation of electrons from one Landau level to another by photons results in a resonant contribution to the magnetic-field-dependent, high-frequency conductivity. It is this phenomenon that is known as *cyclotron resonance*. This article is chiefly concerned with the electronic *scattering rate* τ_{CR}^{-1} that can be deduced from a cyclotron resonance experiment; this is associated with the finite energy width of the Landau levels caused by their limited lifetime. By convention (Ashcroft and Mermin, 1976), the scattering rate is defined as the reciprocal of a notional scattering time τ_{CR} , which is sometimes also referred to as the “Landau-level lifetime.” We shall see that simple-minded first analysis of a cyclotron resonance experiment often yields an *apparent* scattering rate, which may bear little relationship to the actual scattering processes present; it can contain contributions due to experimental factors that mask the true result. Apparent cyclotron scattering rates will be distinguished throughout by the use of the subscript “M,” which stands for “measured”; thus we have the symbol τ_{CRM}^{-1} .

Another concern will be the relationship of τ_{CR}^{-1} to the *apparent* scattering rates deduced from other techniques such as de Haas-van Alphen (or Shubnikov-de Haas) oscillations (τ_{dHvA}^{-1}) and measurements of the electronic conductivity σ (τ_{σ}^{-1}). We shall see that τ_{CR}^{-1} is preferable to τ_{dHvA}^{-1} as a guide to the true energy width of the Landau levels due to scattering. We shall also find that there can be considerable differences between τ_{CR} and τ_{σ} .

In order to keep the discussion as general as possible, we shall refer generally to electrons in a solid as “quasiparticles.” This enables the descriptions that follow to encompass not only both carrier types (electrons, holes) but also systems in which effects such as electron-electron and electron-phonon interactions are significant and describable by Landau Fermi-liquid theory (Gross et al., 1991).

This article deals with cyclotron resonance in metals; the most fundamental definition of a metal is “a solid with a Fermi surface” (Shoenberg, 1984; Singleton, 2001). From the point-of-view of cyclotron resonance, this broad class of materials must be separated into three groups;

1. metals with a high electron density, including elements (Cu, Al etc.) (Häussler and Welles, 1966; Lindholm and Le Page, 1969) and simple alloys (e.g., AuZn, AuBe) (Shoenberg, 1984);
2. intermediate-electron-density systems, often of reduced dimensionality, such as certain oxides [e.g., “high T_c ” cuprate superconductors (Harrison and Chan, 2022; Post et al., 2021), Sr_2RuO_4 (Rzepniewski et al., 2002)], crystalline organic metals (Hill, 1997, 2000; Mola and Hill, 2000; Schrama et al., 2001) and iron-based superconductors (Kimata et al., 2012);
3. low-electron-density systems, including graphene (Russell et al., 2018), topological insulators (Kamenskyi et al., 2020; Mohelský et al., 2020), degenerate semiconductors (Moss and Balkanski, 1994; Singleton, 2001), and semiconductor heterojunctions (Langerak et al., 1988).

The distinction between these three groups results from the ease with which light of the appropriate frequency to excite cyclotron resonance (usually in the GHz to THz range) can penetrate the sample. With the relatively recent advent of high quality epitaxial films, 10s of nm thick, of materials such as cuprates (Post et al., 2021), the boundary between the second and third categories has blurred a little, but nevertheless it is logical for the rest of the article to be arranged as follows. The section “Landau quantization; A brief description” presents a brief introduction to Landau quantization. “Cyclotron resonance in elemental metals and simple metallic alloys” deals with experimental techniques for elemental metals and the extraction of true scattering rates from the apparent rate produced by fitting experimental data. Intermediate- and low-electron-density systems are dealt with in the section “Layered metals and degenerate semiconductor systems”; the experimental techniques and the extraction of scattering rates from data are treated in separate subsections. However, the causes of the difference between τ_{CR} and τ_{dHvA} are similar in both types of “metal,” and so are treated in a common subsection. [Note that, as this article focuses on the extraction of scattering rates from cyclotron resonance, “Layered metals and degenerate semiconductor systems” describes only Faraday geometry measurements (i.e., those in which the radiation propagates parallel to the applied magnetic field). The alternative (and more complex) Voigt configuration is discussed by McKnight and Drew (1981) and Otteneder et al. (2021) and references therein]. Systems containing two or more distinct types of quasiparticles are described in “Many-body effects I: systems with two interacting carrier populations”; the interactions may lead to a single cyclotron resonance rather than two distinct resonances (Cole et al., 1997). Finally, “Many-body effects II: Which effective mass does cyclotron resonance measure?” covers the distinctions between the effective masses measured in different experiments, and “Effects related to cyclotron resonance” mentions two effects closely related to cyclotron resonance.

The history of this subject begins in the 1950s. To avoid recent converts to cyclotron resonance having to “reinvent the wheel” (not always successfully, as some recent papers have shown), literature covering almost the whole of this period is summarized and cited in the text.

In all that follows, I assume that the materials under study are not very magnetic, so that the magnetic induction $B \approx \mu_0 H$, the applied magnetic field, to a good precision. Almost all cyclotron resonance measurements are performed at cryogenic temperatures, for reasons that will become obvious below. Finally, as a significant number of equations is necessary to give a quantitative understanding of the physics involved, Table 1 provides a reference list of the most frequently used symbols in this Chapter.

Table 1 Tabulation of selected symbols.

Symbol	Definition
A	Cross-sectional area of the Fermi surface
$\mathbf{B}$	Magnetic induction
E	Energy of a quasiparticle
$\mathbf{E}$	Electric field
j	A general integer used as a label
$\mathbf{k}$	Quasiparticle wavevector quantum number
$k_{\parallel}$	The component of $\mathbf{k}$ parallel to $\mathbf{B}$
l	Landau-level quantum number
m_{CR}^*	Cyclotron effective mass
m^*	The quasiparticle mass measured in a de Haas-van Alphen experiment
ν	Frequency of photons used to excite cyclotron resonance
q	Quasiparticle charge: $q = \pm e$
σ, σ_{ij}	Conductivity, general element of conductivity tensor
$t_{\perp}, t_i$	Transfer integrals
t	Time
$\mathbf{v}$	Quasiparticle velocity
τ_{CR}	Scattering time associated with Landau-level broadening
τ_{CRM}	Apparent scattering time from a cyclotron resonance measurement
τ_{dHvA}	Apparent scattering time deduced from a de Haas-van Alphen measurement
τ_{σ}	Scattering rate inferred from a zero-field conductivity measurement
ω	Angular frequency of photons used to excite cyclotron resonance
ω_{C}	Cyclotron (angular) frequency
Z	Surface impedance

Landau quantization: A brief description

To gain a qualitative understanding of the principles of the various measurement techniques for cyclotron resonance, it is useful to consider the semiclassical equation of motion of a quasiparticle of charge q , energy E and wavevector quantum number $\mathbf{k}$, subjected to the Lorentz force (Ashcroft and Mermin, 1976; Singleton, 2001):

$$\hbar \frac{d\mathbf{k}}{dt} = q\mathbf{v} \times \mathbf{B}. \quad (1)$$

Here $\mathbf{B}$ is the magnetic induction and $\mathbf{v}$ is the quasiparticle's velocity, defined as

$$\mathbf{v} = \frac{1}{\hbar} \nabla_{\mathbf{k}} E(\mathbf{k}), \quad (2)$$

where $\nabla_{\mathbf{k}}$ is the gradient operator in k -space. Eqs. (1) and (2) imply that (i) the component of $\mathbf{k}$ parallel to $\mathbf{B}$ is constant; and (ii) $\frac{d\mathbf{k}}{dt}$ is perpendicular to $\nabla_{\mathbf{k}} E(\mathbf{k})$. This means that the quasiparticle path is one of constant energy.

The Fermi surface is of course a surface of constant energy (Shoenberg, 1984). Under the action of a magnetic field, quasiparticles on the Fermi surface will remain on that surface while moving on paths which lie in planes perpendicular to the magnetic field (see Fig. 1). The bandstructure of solids is such that in many cases, a constant energy path of this kind will form a closed orbit (or *cyclotron orbit*) of cross-sectional area (in k -space) A (Fig. 1). Standard texts (Ashcroft and Mermin, 1976; Singleton, 2001) show that the angular frequency ω_{C} associated with this periodic orbit is

$$\omega_{\text{C}} = \frac{qB}{m_{\text{CR}}^*}, \quad (3)$$

where

$$m_{\text{CR}}^* = \frac{\hbar^2}{2\pi} \frac{\partial A(E, k_{\parallel})}{\partial E}. \quad (4)$$

The quantity defined in Eq. (4) is known as the *cyclotron mass* or *cyclotron effective mass*.

From a quantum-mechanical point-of-view, the cyclotron orbital frequency corresponds to the quantization of the quasiparticle's motion in the plane perpendicular to $\mathbf{B}$, resulting in an energy spectrum

$$E(\mathbf{B}, k_{\parallel}) = (l + \phi) \hbar \omega_{\text{C}} + E(k_{\parallel}). \quad (5)$$

Fig. 1 Orbits on a Fermi-surface section are in planes perpendicular to **B**. The k -space cross-sectional area of a Fermi-surface orbit is denoted by A (shown in this diagram for the largest one). As will be discussed below, *extremal* orbits, such as the smallest and largest paths around the Fermi surface in this Figure, dominate the cyclotron-resonance spectrum. After Singleton J (2001) *Band Theory and Electronic Properties of Solids*, Oxford: Oxford University Press, Chapters 8 and 9.

Here l is an integer ($l = 0, 1, 2, \dots$) known as the Landau quantum number, ϕ (~ 1) is a phase factor and $E(k_{||})$ is the energy associated with the unaffected wavevector $k_{||}$ in the direction parallel to **B**. The quantization of the quasiparticle's energy in the plane perpendicular to **B** is known as *Landau quantization*, and the energy levels defined by l are called *Landau levels*.

Cyclotron resonance occurs when a photon promotes a quasiparticle from a full state in one Landau level to an empty state in another Landau level. Owing to the fact that photons of the appropriate energy carry very little momentum, such transitions conserve $k_{||}$. Hence, cyclotron resonance occurs when the photon energy ($h\nu$ or $\hbar\omega$) equals $\hbar\omega_c$ or, in some cases, integer multiples of $\hbar\omega_c$ (see below).

Cyclotron resonance in elemental metals and simple metallic alloys

Experimental considerations

The field components of electromagnetic radiation decay with distance z into a conducting material as $\exp.(-z/\delta)$, where $\delta = (\frac{1}{2}\sigma\omega\mu_r\mu_0)^{-\frac{1}{2}}$ is the *skin depth* or anomalous skin depth; here σ is the conductivity of the material (Bleaney and Bleaney, 2013), $\mu_r\mu_0$ is its permeability and ω is the angular frequency of the radiation. Traditional metals have rather high conductivities (Ashcroft and Mermin, 1976); moreover, typical effective masses in metals combined with the magnetic fields readily available in laboratories have meant that frequencies $\omega/2\pi \sim 1\text{--}100$ GHz have tended to be applied in cyclotron resonance experiments. This combination of factors results in a small skin depth; hence, radiation cannot penetrate far into the crystal (Bleaney and Bleaney, 2013). These considerations dictate the geometry of the cyclotron resonance measurement (see Fig. 2); such an configuration is often referred to as the *Azbel'–Kaner geometry* (Häussler and Welles, 1966; Singleton, 2001).

The magnetic field is applied parallel to a surface of the crystal, which is placed in a region of oscillating electric field in a resonant cavity; the E -field **E** of the radiation is arranged to be perpendicular to the quasistatic magnetic field **B** and parallel to the surface. Examination of Eqs. (1) and (2) shows that the projection of an electron's real-space orbit in a plane perpendicular to **B** is the same shape as its k -space orbit rotated by $\pi/2$ radians. The paths of electrons on closed Fermi-surface orbits are therefore helices with axes parallel to **B** in real space.

If the angular frequency of the radiation $\omega = j\omega_c$ where j is an integer, then the electrons on a helical path corresponding to the cyclotron frequency ω_c will receive a "kick" from the radiation's electric field every time they come within a skin depth of the surface; this results in absorption of energy. Usually ω is kept constant and the field is swept, so that absorptions, seen as resonances in the surface impedance, are uniformly spaced in $1/B$ (see Fig. 3).

Extraction of scattering rates

Häussler and Welles (1966), Lindholm and Le Page (1969) and others have demonstrated that a magnetic field which is very accurately parallel to a very flat sample surface is required for a successful measurement; if this is not the case, the helical electron paths drift in and out of the skin depth, causing a smearing of the features in the surface impedance. If the surface is flat, and the magnetic field accurately parallel to it, then the surface impedance Z becomes

$$Z \propto \frac{e^2}{s}, \quad \text{with} \quad s^3 \approx \sum_j p_j R(\lambda_j) + R_{NR} \quad (6)$$

to reasonable accuracy. Here the index j labels the various Fermi-surface orbits involved; in practice, it is found that only *extremal orbits* make a significant resonant contribution (Shoenberg, 1984). Extremal orbits are defined by $dm_{CR}^*/dk_{||} = 0$; frequently these are

Fig. 2 Left: geometry of a cyclotron resonance experiment in a metal. The shaded region indicates the skin depth for the radiation; the helical orbits of the electrons are shown schematically (from Singleton, 2001). Right: a practical implementation of the Azbel-Kaner technique. The sample acts as one wall of a microwave resonant cavity; the whole apparatus is immersed in a liquid helium dewar which sits inside an iron-yoked electromagnet. After Häussler P, and Welles SJ (1966) Determination of relaxation times in cyclotron resonance in copper. *Physics Review* 152: 675.

just the maximum- and minimum-area closed orbits for a particular direction of the magnetic field (see Fig. 1.) In such regions, a large number of electrons have almost identical masses (and thus almost identical ω_c), providing a large contribution to Z . The term R_{NR} encompasses non-resonant processes, while the resonant contributions are described by the function λ_j (Lindholm and Le Page, 1969);

$$\lambda_j = 2\pi \frac{\omega}{\omega_{cj}} \left(\frac{1}{\omega \tau_{jCRM}} + i \right). \quad (7)$$

Note that a cyclotron frequency ω_{cj} and an apparent scattering time τ_{jCRM} has been identified for the j^{th} orbit. As long as the electronic dispersion relationship is nearly parabolic close to the Fermi surface, $R(\lambda_j)$ takes the simple form

$$R(\lambda_j) = \frac{1}{1 - e^{-\lambda_j}}. \quad (8)$$

In practice, the sample orientation is chosen so that only one or two extremal orbits are possible, simplifying the features observed in Z ; an example is shown in Fig. 3.

The above expressions for Z have been used to fit experimental data under a variety of valid approximations; typical examples are given in Häussler and Welles (1966), Lindholm and Le Page (1969) and references therein. It is found that the apparent scattering time τ_{jCRM} encompasses several contributions:

$$\frac{1}{\tau_{jCRM}} = C_{msj}\omega + C_{stj}\omega^{1/3} + \frac{1}{\tau_{impj}} + \frac{1}{\tau_{phononj}} + \frac{1}{\tau_{e-ej}}. \quad (9)$$

The first two terms on the right-hand side of Eq. (9) are due to so-called “mass spread” ($C_{msj}\omega$) and the effects of surface roughness ($C_{stj}\omega^{1/3}$). The former term has the following origin; as has been mentioned above, the resonance spectrum is dominated by extremal orbits about the Fermi surface, defined by $dm_{CR}^*/dk_{\parallel} = 0$. In such regions, a large number of electrons have almost identical masses (and thus almost identical ω_c), providing a large contribution to Z . The fact that higher derivatives of m_{CR}^* do not vanish in real Fermi surfaces causes “mass-spread”; a distribution of cyclotron frequencies leads to a smearing of the resonant features which at first sight looks as though it is due to scattering. This effect is represented by the term $C_{msj}\omega$ in Eq. (9).

Fig. 3 Combined cyclotron resonance signals from extremal belly orbits B' and neck orbits N in Copper; the field is in the $[111]$ direction. The upper curve is a theoretical simulation that shows the two contributions separately (dashed and dotted curves) and combined (solid curve). The lower part of the figure shows experimental data. The fortuitous factor of 3 between the cyclotron periods of the two orbits facilitates separation of the two contributions. After Häussler P, and Welles SJ (1966) Determination of relaxation times in cyclotron resonance in copper, *Physics Review* 152: 675.

Because both the mass-spread and surface roughness terms consist of a constant times ω raised to a small power, they may be distinguished from the other (frequency-independent) contributions by measuring the surface impedance at more than one frequency.

The last three (frequency independent) terms in Eq. (9) are caused by the actual scattering mechanisms; their sum is τ_{CRj}^{-1} . A weighted average of all of the electron-impurity scattering processes leads to the term τ_{impj} , while τ_{phononj} and $\tau_{\text{e-ej}}$ are due to electron-phonon scattering and electron-electron scattering events respectively. The three terms may be distinguished by observing their temperature dependences;

$$\frac{1}{\tau_{\text{impj}}} = \text{constant}, \quad \frac{1}{\tau_{\text{phononj}}} \propto T^3 \quad \text{and} \quad \frac{1}{\tau_{\text{e-ej}}} \propto T^2. \quad (10)$$

The origins of the temperature power laws for these mechanisms is dealt with in standard texts (e.g., Ashcroft and Mermin, 1976; Singleton, 2001).

Layered metals and degenerate semiconductor systems

Fermi surfaces and resonant cavity techniques

The past 40 years has witnessed continuous great interest in layered materials; there are many correlated-electron systems which have very anisotropic electronic bandstructure. Examples include the “high- T_c ” cuprates (Harrison and Chan, 2022; Post et al., 2021), iron-based superconductors (Mancini and Citro, 2017), crystalline organic metals and superconductors (Lebed, 2007; Singleton, 2000), and layered ruthenates (Rzepniewski et al., 2002) and manganites (Kimura and Tokura, 2000). In the context of the current discussion, such systems have two distinctive features.

1. Typically, their quasiparticle densities are rather lower than those in elemental metals; hence their skin depths tend to be larger, and the effects of screening are reduced (Rzepniewski et al., 2002; Schrama et al., 2001).
2. These systems may often be described by a tight-binding Hamiltonian in which the ratio of the average interlayer transfer integral $t_\perp$ to the average intralayer transfer integral $t_\parallel$ is $\ll 1$. This results in very anisotropic electronic properties (Goddard et al., 2004; Singleton, 2000).

Fig. 4 shows the cross-section of the Fermi surface of a typical (and simple) example, the organic superconductor κ -(BEDT-TTF)₂Cu(NCS)₂, parallel to the highly conducting planes. The Fermi surface consists of both open and closed sections; it is customary to label such sections “quasi-one-dimensional” and “quasi-two-dimensional” respectively (Singleton, 2000, 2001). The names arise because the Fermi surface is a surface of constant energy, and so Eq. (2) shows that the velocities of quasiparticles at the Fermi surface will be directed perpendicular to it. Therefore, referring to Fig. 4, quasiparticles on the closed Fermi-surface pocket can possess velocities which point in any direction in the (k_b, k_c) plane; they have freedom of movement in two dimensions and are said to be *quasi-two-dimensional*. By contrast, quasiparticles on the open sections have velocities predominantly directed parallel to k_b and are *quasi-one-dimensional*.

Thus far we have only considered a cross-section through the Fermi surface parallel to the highly-conducting planes (Fig. 4). In the interlayer direction (also known as the *interplane* direction), the dispersion is very small, due to the small interlayer transfer integrals. For the purpose of this discussion, we choose a simple model of the quasiparticle dispersion, written as

$$E(\mathbf{k}) = E(k_x, k_y) - 2t_\perp \cos(k_z d) \quad (11)$$

where k_x, k_y and k_z are the components of the wave vector parallel (k_x, k_y) and perpendicular (k_z) to the conducting planes and $t_\perp$ is again the interlayer transfer integral [For examples of more realistic interlayer dispersion see e.g., Goddard et al., 2004 and Grissonnanche et al., 2021]. The presence of dispersion in the interlayer direction will result in a slight warping of the Fermi surface, shown schematically for a closed pocket in Fig. 5a.

As before, when a magnetic field is introduced, Eqs. (2) and (1) indicate that the k -space path of the quasiparticle is defined by the intersections of surfaces of constant energy with planes perpendicular to $\mathbf{B}$. Therefore, for almost all directions of the magnetic field, quasiparticles on the closed sections of Fermi surface will be able to complete closed k -space orbits in the plane perpendicular to $\mathbf{B}$ (see Fig. 5(a)); in contrast, the quasiparticles on quasi-one-dimensional sections of Fermi surface will not complete closed orbits (see Fig. 5(b)).

The experimental detection of cyclotron resonance depends on the effect that the quasiparticle paths have on the high-frequency conductivity. Eq. (2) shows that the quasiparticle velocity must always be perpendicular to the Fermi surface. Hence, as the

Fig. 4 Brillouin zone and Fermi-surface of κ -(BEDT-TTF)₂Cu(NCS)₂, showing the open, quasi-one-dimensional sections, and the closed, quasi-two-dimensional pocket (Singleton, 2001, 2000).

Fig. 5 (a) Schematic side view of the warping (corrugation) of a closed section of Fermi surface caused by finite interplane transfer integrals. The arrows indicate the velocities of a quasiparticle following a closed orbit about the Fermi surface in a plane perpendicular to the magnetic field $\mathbf{B}$. (b) An open section of Fermi surface. In an in-plane magnetic field, quasiparticles will be driven across the Fermi surface, so that their velocities (shown by arrows) will rock from side to side. From Singleton J (2000) Studies of quasi-two-dimensional organic conductors based on BEDT-TTF using high magnetic fields. *Reports on Progress in Physics* 63(8): 1111.

quasiparticles traverse the orbits shown Fig. 5(a) and (b), the corrugations of the Fermi surface cause their velocity vectors to rock back and forth. It is the evolution of the quasiparticle velocities with time that affect the conductivity of the system, and thus enable cyclotron resonance to be detected. Cyclotron resonance is of course associated with the closed orbits of Fig. 5(a); the open orbits shown on Fig. 5(b) lead to a related resonant contribution to the high-frequency magnetoconductivity, known as a *Fermi-surface traversal resonance* (FTR). (To find out more about FTRs, see Schrama et al. (2001) and references therein.)

As mentioned above, the low electron densities of these materials compared to those in typical elemental metals results in a larger skin depth; hence, with careful planning, an experiment can be arranged in which a substantial fraction of a typical single-crystal sample (volume $\sim 0.01\text{--}0.1\text{ mm}^3$) can be penetrated by radiation with frequencies $\sim 10\text{--}100\text{ GHz}$. Therefore the experimental response is typically much more determined by the frequency-dependent *bulk conductivity*, rather than the surface impedance.

The evolution of the quasiparticle's velocity can be related to its contribution to the frequency-dependent conductivity of the metal using the frequency-dependent Boltzmann transport equation (also known as the Chambers Equation) (Nam et al., 2001; Schrama et al., 2001).

$$\sigma_{ij}(\omega) = \frac{e^2}{4\pi^3} \int d^3k \left[-\frac{\partial f_0(\mathbf{k})}{\partial E(\mathbf{k})} \right] v_i(\mathbf{k}, 0) \int_{-\infty}^0 v_j(\mathbf{k}, t) \cos(\omega t) e^{t/\tau} dt \quad (12)$$

Here, τ is a relaxation time (not necessarily the same as τ_{CR}), $v_i(\mathbf{k}, t)$ is the i th component of the velocity of a quasiparticle with wave vector $\mathbf{k}$ at time t and $f_0(\mathbf{k}) = (e^{(E(\mathbf{k}) - E_F)/k_B T} + 1)^{-1}$ is the Fermi function. This is an integral (over all states at the Fermi surface) of the velocity-velocity correlation function for each Fermi-surface orbit.

The mechanism for detecting cyclotron resonance can be understood by examining Fig. 5(a). For a general direction of the magnetic field (as shown in Fig. 5) the corrugations of the Fermi cylinder will cause a quasiparticle's interplane (z) velocity to acquire an oscillatory component as it is driven round an orbit about the Fermi cylinder. These oscillatory interplane velocities contribute at a particular frequency (and, perhaps, its harmonics) to Eq. (12); hence they are detectable as resonances in the high-frequency interplane conductivity $\sigma_{zz}(\omega)$.

Note that if the corrugations are not exactly perpendicular to the cylinder axis, then even a magnetic field parallel to the cylinder axis (i.e., in the interplane z direction) will induce an oscillatory interplane component of the quasiparticle velocity and hence a resonant response in σ_{zz} . This resonant response in σ_{zz} occurs at integer harmonics of the cyclotron frequency, $j\omega_C$; these can be caused both by the orbit traversing j corrugations or by the presence of a non-sinusoidal corrugations.

Cyclotron resonance harmonics are also possible in the *intraplane* high-frequency conductivity components σ_{xx} and σ_{yy} ; this results from Fermi-surface cross-sections that are non-elliptical (Nam et al., 2001). Unless the Fermi surface lacks inversion symmetry, this mechanism generates only *odd* harmonics. Both types of cyclotron resonance mechanism with their attendant harmonics have been reported in the layered perovskite Sr_2RuO_4 (Rzepniewski et al., 2002).

Cyclotron resonance in such materials is observed using millimeter-wave cavity perturbation techniques (see Fig. 6) such as those described in Schrama et al. (2001) and Mola and Hill (2000) (both applied to crystalline organic metals) and Kimata et al. (2012) (applied to the iron-based superconductor KFe_2As_2). Such measurements probe the bulk conductivity properties of anisotropic conductors. Changes in the dissipation of the cavity (Q factor) are measured as a function of an external quasistatic magnetic field $\mathbf{B}$ with the millimeter-wave frequency ν held constant. It is assumed that changes in the dissipation of the cavity are due to changes in the dissipation of the sample inside.

Fig. 6 Experimental configuration for cyclotron resonance in a layered metal (Schrama et al., 2001). Left: (a) the sample is placed in the cavity with the oscillating millimeter-wave field H_{osc} in the highly conducting planes ($\parallel$ direction). (b) Both in-plane and interplane oscillating currents J_{osc} are induced. In the skin-depth regime in-plane currents flow within a surface layer of thickness $\delta_{\parallel}$ parallel to large sample faces, and interplane currents flow within a thicker layer $\delta_{\perp}$ parallel to sample edges. Right: schematic of the vertical cross section of a rectangular cavity that can be used for cyclotron resonance measurements of a layered metal. The cavity is placed between two waveguides that lead to the source (HG) and detector (HM). The cavity is held in this position by two Rexolite cylinders of 3 mm diameter which are fitted in the recessed area around the coupling holes and which extend through the holes (3 mm diameter) in the waveguides. The sample is placed on a thin mylar film in the cavity center, in the H -field antinode of the TE_{102} mode of the cavity. The advantage of such a cavity system is that it allows the cavity and the sample to be rotated in the vertical quasistatic magnetic field (provided by either a superconducting or a Bitter magnet); because the cavity rotates, the sample remains in the same high-frequency electrodynamic environment. Hence, the magnetic-field-orientation dependence of the cyclotron resonance can be studied. (The mechanism for rotating the cavity has been omitted for clarity.)

The sample is placed in the cavity such that the millimeter-wave magnetic field H_{osc} is polarized parallel to the sample's highly conducting planes (perpendicular to the c -axis) (see Fig. 6). The response of an anisotropic conductor in this electromagnetic environment is understood by examining the polarizations of the currents induced in the sample by H_{osc} . For H_{osc} parallel to the (a , b) plane (the highly-conducting plane), both in-plane and interlayer currents are induced (Fig. 6). These currents flow within a distance $\sim \delta$ (here δ is the skin depth) from the sample's edges and faces (Fig. 6(b)). The in-plane ($\delta_{\parallel}$) and interlayer ($\delta_{\perp}$) skin depths give information about σ_{zz} and a combination of σ_{xx} and σ_{yy} respectively.

(All of the above applies to measurements of single crystals. With the more recent availability of epitaxial films, tens of nm thick, of materials such as cuprate superconductors, simple transmission measurements are also possible (Post et al., 2021); see the section "Experimental techniques: Pulsed measurements".)

Extraction of the apparent scattering rates in layered metals

As described by Schrama et al. (2001) and Mola and Hill (2000), changes in the Q factor of the resonant cavity can be related via the skin depths to changes in the components of the sample's conductivity tensor. Generally, the most reliable method of extracting the apparent scattering time is to fit the high-frequency conductivity directly (Edwards et al., 2003; see Fig. 7); for example, McKenzie and Moses (1999) and Moses and McKenzie (1999) suggest an interlayer conductivity

$$\frac{\sigma_{zz}(\omega)}{\sigma_{zz}(\omega=0)} = \sum_{-\infty}^{\infty} \frac{[J_j(k_F c \tan \theta)]^2}{1 + (\omega - j\omega_c \cos \theta)^2 \tau_{CRM}^2} \quad (13)$$

for layered materials with weak interlayer coupling that has been successfully applied to organic conductors. Here j is an integer, J_j is the j th Bessel function, c is the interlayer lattice spacing, k_F is the Fermi wavevector and θ is the angle between the magnetic field and the normal to the conducting planes. Note that the apparent scattering time τ_{CRM} is always a fit parameter in such methods.

Cyclotron resonance in semiconductors, candidate topological insulators and other low carrier-density systems

Experimental details: quasistatic measurements

The number densities of carriers in semiconductor samples are much lower than those in metals, so that the radiation can completely penetrate even large crystals (Moss and Balkanski, 1994; Singleton, 2001). Similar considerations apply to topological insulators such as Bi_2Te_3 (see Kamenskyi et al. (2020) and Mohelský et al. (2020) and references therein), where the desired surface states are often accompanied by a low density of quasiparticles in the bulk of the sample. In systems such as graphene

Fig. 7 (a) Cyclotron resonance data for the quasi-two-dimensional organic conductor β'' -(BEDT-TTF) $_2$ SF $_5$ CH $_2$ CF $_2$ SO $_3$. The data are in the form of cavity transmission vs. magnetic field; the frequency of the measurement is 71 GHz, and the temperature is 1.5 K. Field sweeps for several orientations θ of the cavity and sample in the quasistatic field are shown (see Fig. 6); $\theta = 0$ corresponds to the field being perpendicular to the highly-conducting planes of the sample. The sharp slope downwards and small minimum at low fields are associated with the superconducting-to-normal transition of the sample and a background feature in the cavity response. The small sharp feature is the conduction-electron spin resonance of the sample. The cyclotron resonances are the broader features at higher fields. (b) A model of the data using Eq. (13) with k_F calculated for this particular sample orientation and $\tau_{\text{CRM}} = 1.22 \times 10^{-12}$; the latter value was derived from a simple treatment (see Eq. (15)) of Shubnikov-de Haas oscillations from the same sample. Note how the predicted resonance widths are similar to the experimental ones. (c) A repeat of (b) for $\tau = 7 \times 10^{-12}$ s; note how the predicted resonance widths are too broad. All panels show curves for $\theta = 0$ (lowest), 10, 20, 30, 40, 50, 60 and 70 degrees (highest). After Edwards RS, Herlach F, and Miura N (2003) High magnetic fields, science and technology, Vol. 2, Theory and Experiments, Singapore: World Scientific.

Fig. 8 Simplified schematic of a cyclotron resonance experiment in a semiconductor or other low-carrier-density metal. The light source may be monochromatic (e.g., optically-pumped FIR laser, backward-wave oscillator), in which case the field is swept. Alternatively, a broadband Fourier-transform infrared spectrometer may be used with the applied magnetic field held constant. The field is shown applied parallel to the light propagation direction, i.e., the Faraday geometry, as is the case for the vast majority of cyclotron resonance studies. Transmitted radiation is detected by the bolometer. In practice, the sample will usually be inside a re-entrant flow cryostat to allow the cyclotron resonance to be measured as a function of sample temperature. After Singleton J (2001) Band Theory and Electronic Properties of Solids, Oxford: Oxford University Press, Chapters 8 and 9.

(see, e.g., Russell et al. (2018) and citations therein) or semiconductor heterostructures or superlattices (Langerak et al., 1988; Moss and Balkanski, 1994), the quasiparticles inhabit a few layers (or even just a single layer) of $\sim$ nm thickness so that the overall number of carriers in a sample is very small; again, the radiation fills the whole sample. In all of these cases, a simple transmission arrangement is often adopted (see Fig. 8). Experiments are carried out either by using a fixed-frequency source [such as an optically-pumped far-infrared laser, which can give a number of monochromatic laser lines in the wavelength range 30–1000 μ m (Langerak et al., 1988), or a free-electron laser (FEL) (Vaughan et al., 1996)] and sweeping the magnetic field [see Fig. 9(a)], or by fixing the magnetic field and varying the energy of the radiation [see Fig. 9(b)] using, e.g., a Fourier-transform infrared spectrometer. The magnetic field is provided either by a superconducting magnet ($B \lesssim 18$ T) or, in user facilities, by a Bitter or polyhelix magnet.

As the whole of the cyclotron orbit experiences the electric field of the radiation (*c.f.* the situation in metals; see above), the quantum-mechanical selection rule for the Landau-level quantum number ($\Delta l = \pm 1$) holds. Thus the resonance condition is

Fig. 9 (a) Illustration of cyclotron resonance in a swept-field, monochromatic light-source experiment. In a simple semiconductor system, the full width at half maximum of the resonance in such measurements is $2/\mu$, where μ is the mobility (see discussion). (b) Cyclotron resonances in a GaAs-(Ga,Al)As heterojunction at $T = 4.2$ K; the magnetic field has been applied perpendicular to the two-dimensional electron layer, which has an areal carrier density $\approx 9 \times 10^{10} \text{ cm}^{-2}$. The data have been recorded by fixing the magnetic field at 1.5, 2, 3, 4, and 5 T (the resonances in the figure have the corresponding field labeled above them); at each field, a Fourier-transform infrared spectrometer has then been used to record the transmission of the sample as a function of energy. Figure redrawn from Singleton J (2001) *Band Theory and Electronic Properties of Solids*, Oxford: Oxford University Press, Chapters 8 and 9.

$$\hbar v \equiv \hbar \omega = \hbar \omega_c = \frac{\hbar e B}{m_{\text{CR}}^*}, \quad (14)$$

where $v(\omega)$ is the frequency (angular frequency) of the radiation.

As stated in the Introduction, in degenerate semiconductor systems (e.g., heterojunctions) and candidate topological insulators, free carriers are present even at low temperatures; typical cyclotron resonance data are shown for the former in Fig. 9(b). However, it is worth mentioning that in lightly doped semiconductor samples, the carriers must be excited into the bands by either raising the temperature to cause the impurities to ionize (but not so far as to broaden the Landau levels) or by additionally illuminating the sample with above-band-gap radiation (Bleaney and Bleaney, 2013; Moss and Balkanski, 1994; Singleton, 2001).

Experimental techniques: Pulsed measurements

As an alternative to the quasistatic optical methods described in the previous section, ultrashort pulsed lasers are used to generate broadband pulses of THz radiation. This THz *time-domain spectroscopy* (THz-TADS) technique has been combined with both constant and pulsed magnetic fields to observe cyclotron resonance. Fig. 10 shows an experimental set-up in which a small pulsed magnet is incorporated into the free-space beam path of a THz-TADS spectrometer (Post et al., 2021). The field is applied parallel to the light propagation direction (i.e., the Faraday geometry). To rapidly detect the THz waveform at peak field, a THz-TADS system based on electronically controlled optical sampling (ECOPS), wherein the timing delay between the two ultrafast optical pulse trains that drive the THz emitter and receiver can be electronically modulated very quickly. When synchronized to the magnetic field, the THz waveform can be recorded at multiple field values during a single magnet pulse.

Following standard procedures, the measured THz electric field is Fourier transformed to yield the frequency-dependent complex optical transmission. The incorporation of two linear polarizers, P1 and P2, allows the sample's complex conductivity to be extracted from the transmission data in right- and left-circularly polarized bases, which correspond to $\sigma_r(\omega)$ and $\sigma_l(\omega)$, the cyclotron-active and -inactive modes, respectively. The direct measurement of both real and imaginary components of the frequency-dependent conductivity is unique to THz-TADS—it is not possible with conventional Fourier-transform infrared spectroscopy—and permits the resolution of small cyclotron frequency shifts, even when $\omega_c \tau < 1$.

Examples of THz-TADS applied to cyclotron resonance of a candidate topological insulator $\text{Pb}_{0.5}\text{Sn}_{0.5}$ and a thin film of a cuprate superconductor are given in Cheng et al. (2019) and Post et al. (2021) respectively.

Extraction of apparent scattering times

In some situations where both the scattering time (or mobility) and the density of the carriers are low (e.g., bulk degenerate semiconductors), the measured linewidth of the cyclotron resonance can give information about the true scattering rate τ_{CR}^{-1} directly. Via the uncertainty principle, the scattering induces a frequency uncertainty $\Delta\omega_c \sim \tau_{\text{CR}}^{-1}$. If the experiment is a fixed-frequency, swept-field one, this translates to an uncertainty (i.e., resonance width) in magnetic field of $\Delta B = \Delta\omega_c m_{\text{CR}}^* / q \sim m_{\text{CR}}^* / q \tau_{\text{CR}}$. Provided that $m_{\text{CR}}^* \approx$ the effective mass for linear motion (and this is often true in direct-gap semiconductors like GaAs) it is apparent that ΔB is of order the reciprocal of the carrier mobility. More precise derivations show that the full width at half maximum is in fact twice the reciprocal of the mobility.

However, in systems such as GaAs-(Ga,Al)As heterojunctions, where both the scattering time (or mobility) and the equivalent three-dimensional carrier density in the two-dimensional layer are relatively large, there is a very marked contribution to the cyclotron resonance linewidth due to the impedance mismatch between the vacuum and the carriers (Langerak et al., 1988). The effect is illustrated in Fig. 11; often this “mismatch” contribution to the linewidth eclipses that due to scattering. The problem can be

Fig. 10 (a) Experimental schematic of an ECOPS-based THz-TCDS spectrometer adapted for cyclotron resonance. A small pulsed magnet powered by a 20 kJ capacitor bank is incorporated into the beam path. Broadband THz optical pulses generated by the transmitter are linearly polarized (by P1) and focused through the sample in the magnet bore. They are then directed through a second polarizer (P2) and detected by the gated receiver (Rx). Parabolic collimating and focusing mirrors are not shown. (b) The field profile of a 31 T magnet pulse (blue, left axis) is plotted along with the simultaneously measured THz electric field (right axis). (c) THz electric field measured at zero field (black) and at 31 T (red). The upper x axis shows actual laboratory time. The ECOPS system sweeps the effective time delay through 5 ps in $\approx 30 \mu\text{s}$. After Post KW, Legros A, Rickel DG, Singleton J, McDonald R, He X, Bozovic I, Xu X, Shi X, Armitage NP, Crooker S (2021) Observation of cyclotron resonance and measurement of the hole mass in optimally doped $\text{La}_2\text{-xSr}_x\text{CuO}_4$, *Physical Review B* 103: 134515.

ameliorated by evaporating a surface metallic layer of carefully-chosen thickness on the sample (Watts et al., 1992), but the most reliable method to extract the apparent scattering rate is to perform a full modeling of the transmission or reflectivity of the sample (Langerak et al., 1988) as carried out in Fig. 11.

A similar approach is used with the THz-TCDS data; the scattering time is extracted via a direct fit of the cyclotron resonance lineshape (Cheng et al., 2019; Post et al., 2021).

Contributions to the apparent scattering rate in layered metals, semiconductor heterostructures and other similar systems

Comparisons with other methods

A measure of the scattering rate in metallic systems is often derived from the rate at which magnetic quantum oscillations (such as de Haas-van Alphen oscillations) grow in amplitude with increasing magnetic field; the dominant term in the Lifshitz-Kosevich formula (Shoenberg, 1984) describing this phenomenon is $\exp[-14.7 m_{\text{CR}}^* T_D / B]$ (SI units). The constant describing the phase-smearing of the oscillations due to Landau-level broadening is the so-called *Dingle temperature*, T_D .

If one were to assume that T_D is due *solely* to scattering (i.e., the energy width of the Landau levels detected by the de Haas-van Alphen effect is associated only with their finite lifetime due to scattering) then T_D would be related to the scattering rate τ_{dHvA}^{-1} by the expression

Fig. 11 Model calculations for the reflectivity of a GaAs-(Ga,Al)As heterojunction at a photon energy $\hbar\omega = 10.43$ meV for several values of the areal electron density N_s ; each calculation is displaced vertically for clarity. The cyclotron resonance shows up as a dip in the reflectivity signal at low N_s but becomes a peak at higher carrier densities. Note that although the scattering rate is kept constant ($\tau = 10.6$ ps), the full width at half-maximum of the resonance grows with increasing N_s . Similar effects are seen in the transmission of the sample. The left-hand inset shows an expansion of the low-density part of the main figure; the right-hand inset contains experimental data for a photon energy of 31.05 meV and $N_s = 0.3 \times 10^{11} \text{ cm}^{-2}$. After Langerak CJGM, Singleton J, van der Wel PJ, Perenboom JAAJ, Barnes DJ, Nicholas RJ, Hopkins MA, and Foxon CTB (1988) Carrier-concentration-dependent electron-LO-phonon coupling observed in GaAs-(Ga,Al)As heterojunctions by resonant-polaron cyclotron resonance, *Physical Review B* 38: 13133; see also Post KW, Legros A, Rickel DG, Singleton J, McDonald R, He X, Bozovic I, Xu X, Shi X, Armitage NP, Crooker S (2021) Observation of cyclotron resonance and measurement of the hole mass in optimally doped La2-xSrxCuO4, *Physical Review B* 103: 134515.

$$T_D = \frac{\hbar}{2\pi k_B \tau_{\text{dHvA}}} \quad (15)$$

In many experimental works, it is assumed that the τ_{dHvA} deduced from T_D in this way is a true measure of scattering rate; we shall see shortly that it is *not*!

Another measure of the scattering rate can be found by measuring the zero-magnetic-field electrical conductivity; in layered systems, one must be careful to ensure that this is the *intralayer* component of the conductivity (Singleton, 2000). If there is a dominant single carrier type of known density n , then the Drude expression $\sigma = nq^2\tau_\sigma/m^*$ can be used to estimate τ_σ . It is universally found that $\tau_\sigma \geq \tau_{\text{dHvA}}$; in some cases such as semiconductor heterojunctions, τ_σ can be one to two orders of magnitude greater than τ_{dHvA} .

Finally, if these scattering times are compared with the τ_{CRM} deduced from cyclotron resonance experiments, the following is found;

$$\tau_\sigma \geq \tau_{\text{CRM}} \geq \tau_{\text{dHvA}} \quad (16)$$

For some layered metals (Hill, 1997, 2000), the τ_{CRM} measured in cyclotron resonance has been found to be four to ten times larger than τ_{dHvA} . Another example is shown in Fig. 7, where the insertion of the scattering rate inferred from Shubnikov-de Haas oscillations (Fig. 7(b)) into a model for the cyclotron resonance produces linewidths that are much too broad. A more realistic linewidth is obtained with a longer scattering time (Fig. 7(c)).

The importance of spatial inhomogeneities

The difference between any measurement of Landau-level broadening and the scattering rate deduced from a conductivity measurement is easy to grasp; a quasiparticle will be removed from a Landau-level eigenstate by *any* scattering event, small- or large-angle. Conversely, small-angle scattering events hardly affect the conductivity, because they cannot randomize a quasiparticle's excess forward momentum (see Fig. 12 and standard texts [e.g., Ashcroft and Mermin (1976), Singleton (2001)]). In the most thoroughly-studied systems of reduced dimensionality, semiconductor heterostructures and Si MOSFETs, it is found that $\tau_\sigma \approx \tau_{\text{dHvA}}$ in systems in which large-angle scattering (e.g., due to impurities in the conducting channel) dominates. On the other hand, in systems in which small-angle scattering (e.g., due to remote impurities) is pre-eminent, $\tau_\sigma \gg \tau_{\text{dHvA}}$. Having seen this, the remaining task is to explain how two measurements of Landau level width (cyclotron resonance and de Haas-van Alphen effect) can yield such different answers.

At least some of the difference between τ_{CRM} and τ_{dHvA} turns out to be due to spatial inhomogeneities or potential fluctuations. Screening is less effective in systems containing low densities of quasiparticles (such as layered metals or semiconductor heterojunctions) (Harrison and Singleton, 2001), compared to that in elemental metals; hence variations in the potential experienced by

Fig. 12 Left: schematic of the difference in scattering rates in Landau quantization and electrical conductivity. Any scattering event (small- or large-angle) during the cyclotron orbit terminates that particular Landau state. By contrast, small-angle scattering is not effective at randomizing the quasiparticle's excess forward momentum in a transport (conductivity) measurement. Right: a cartoon of the effect of spatial inhomogeneities on Landau-level widths and energies. The variations in the potential experienced by the electrons make the Landau levels (shaded curves) move up and down in energy as one moves through the sample. As the field is swept, the levels will move up through the chemical potential μ and depopulate, resulting in the de Haas-van Alphen and Shubnikov-de Haas effects. The Dingle Temperature essentially parameterizes the movement of the *total energy width of a Landau level* through μ ; hence it will measure a width that includes the energy variation due to inhomogeneities. By contrast, cyclotron resonance (shown by vertical arrows) is a “vertical” transition; it will measure just the true width of the Landau levels due to scattering (represented by shading).

the quasiparticles can lead to a spatial variation of the Landau-level energies (see Fig. 12). Even in the (hypothetical) complete absence of scattering, Harrison and Singleton (2001) (for example) shows that this spatial variation would give the Landau level a finite energy width (see Fig. 12) and therefore lead to an apparent Dingle temperature

$$T_D = \frac{\bar{x}[1 - \bar{x}]F'(\bar{x})^2 a}{\pi k_B m^*} \sqrt{\frac{\hbar e^3}{2F}}. \quad (17)$$

Here F is the magnetic-quantum-oscillation frequency, and $F' = dF/dx$; x represents the (local) fractional variation of the quasiparticle density due to the potential fluctuations and $\bar{x}$ is its mean.

The Dingle temperature measured in experiments will therefore usually represent a combination of the effects described by Eqs. (15) and (17). Hence the simple-minded use of Eq. (15) to yield τ_{dHvA} from T_D will tend to result in a parameter that is an overestimate of the true scattering rate (see Fig. 12). By contrast, cyclotron resonance (shown by vertical arrows in Fig. 12) is a “vertical” transition (due to the very low momentum of the photon); it will measure just the true width of the Landau levels due to scattering (represented by shading).

Scattering times in angle-dependent magnetoresistance oscillations

Angle-dependent magnetoresistance oscillations are observed by measuring the resistance of a sample as it rotates in a fixed magnetic field (Blundell and Singleton, 1996; Lebed, 2007; Singleton et al., 2007); the technique is popular in the anisotropic materials (e.g., cuprates (Grissonnanche et al., 2021), organic metals etc.) discussed in this Section. Though some AMRO-like phenomena occur due to field-induced dimensional crossovers (Lebed, 2007), the majority of AMRO data are modeled using the Boltzmann transport equation (i.e., the zero-frequency version of Eq. (12)) (Blundell and Singleton, 1996; Goddard et al., 2004). This is an integral over all states at the Fermi surface of the velocity-velocity correlation function for each Fermi-surface orbit; it can change dramatically as the direction of the magnetic field is changed, because this alters the paths of all the orbits (see Fig. 13).

The scattering time is an input parameter in simulations of AMRO, and it is found that $\tau_{\text{AMRO}} > \tau_{\text{dHvA}}$. For example, experiments on the same single crystal of the organic superconductor $\kappa\text{-(BEDT-TTF)}_2\text{Cu(NCS)}_2$ revealed $\tau_{\text{dHvA}} \approx 2.3$ ps (Goddard et al., 2004) and $\tau_{\text{AMRO}} \approx 3.5$ ps (Singleton et al., 2007) under similar conditions of temperature and field. Part of this difference is likely to occur because the field-induced paths across the Fermi surface are less affected by small-angle scattering than are Landau-level states [see Fig. 12(a)]. In addition, whereas the effects of spatial inhomogeneities contribute to the apparent Landau-level width [see Fig. 12(b)], they may well be averaged out by the ensemble of Fermi-surface orbits that determine AMRO features (Blundell and Singleton, 1996). Similar considerations apply in the modeling of linear magnetoresistance in correlated-electron systems [see Singleton, 2020 and references therein].

Many-body effects I: Systems with two interacting carrier populations

Cyclotron resonance data can sometimes be difficult to interpret in systems containing two distinct quasiparticle populations that interact. An example is given by p-doped GaAs-(Ga,Al)As heterojunctions, containing two hole spin subbands with differing

Fig. 13 Illustration of the field-induced motion of quasiparticles across a quasi-one-dimensional Fermi-surface section. The magnetic field lies at two different angles in the plane of the Fermi surface; as discussed earlier (see Eq. 1), the quasiparticles move across the Fermi surface in a plane perpendicular to the magnetic field. The quasiparticle velocities are directed perpendicular to the Fermi surface (see Eq. 2) and are shown as arrows. The velocity is more effectively averaged when electrons are not traveling along the axis of the Fermi-surface corrugation (a) than when they are (b). Analogous phenomena are produced by field-induced orbits on quasi-two-dimensional Fermi surfaces.

effective masses. One would expect two distinct cyclotron resonances; however, depending on temperature, photon energy and field, a single resonance is frequently observed. This results from the interactions between the two types of quasiparticle; the overall energy of the system is reduced if these interactions constrain both populations to have the same cyclotron frequency.

Cole et al. (1997) gives expressions for the high-frequency magnetoconductivity $\sigma(\omega)$ that can be very generally used to treat such situations; they allow the scattering rates and effective masses for each type of quasiparticle to be extracted, and also enable their interactions to be quantified.

Many-body effects II: Which effective mass does cyclotron resonance measure?

Cyclotron resonance is potentially a very interesting measure of the interactions in narrow-bandwidth metallic systems. In a translationally-invariant system, the mass m_{CR}^* measured in a cyclotron resonance experiment should not contain any contribution from the interactions between the carriers themselves; this is known as *Kohn's theorem* (Baym and Pethick, 2004; Post et al., 2021). In the language of Fermi-liquid theory, in such a situation, cyclotron resonance measures the dynamical mass $m_{\lambda\text{CR}}$, whereas a thermodynamic measurement such as the de Haas-van Alphen oscillations reveals the effective mass m^* , which also contains contributions from the Coulomb interactions between the quasiparticles (Gross et al., 1991).

A simple bandstructure calculation essentially uses ions and molecules which are rigidly fixed in a perfectly periodic arrangement to obtain a periodic potential and hence the bands. However, the ions and/or molecules in a substance will in general be charged, or at the very least possess a dipole moment; as an electron passes through the solid, it will tend to distort the lattice around it owing to the Coulomb interactions between the ions and molecules and its own charge. This leads to the electron being accompanied by a strain field as it moves through the substance; alternatively one can consider the electron being surrounded by virtual phonons. This affects the way in which the electron can move through the substance and usually acts to increase the apparent mass.

In the following, for consistency we deal with the orbitally averaged (cyclotron) mass; other “effective masses” (e.g., for linear motion) will be renormalized in an analogous way. If m_{bCR} is the cyclotron mass calculated in the bandstructure calculations, then the electron-lattice interactions discussed above will result in a cyclotron dynamical mass, $m_{\lambda\text{CR}}$, where

$$m_{\lambda\text{CR}} \approx (1 + \lambda)m_{\text{bCR}}, \quad (18)$$

where λ is an electron-phonon coupling constant.

The interactions between the electrons themselves must also be taken into account. As electrons are highly charged, they will repel each other; therefore, as an electron is moved across a sample under consideration by an external force, in effect there will be a backflow of electrons caused by this repulsion. Thus, it is “harder” to move electrons about than expected, i.e., their apparent effective mass is heavier than $m_{\lambda\text{CR}}$. The effective masses m^* measured in experiments such as the de Haas-van Alphen effect include this contribution from the interactions between the electrons, so that

$$m^* \approx \left(1 + \frac{F_s^1}{3}\right)m_{\lambda}, \quad (19)$$

where F_s^1 is a constant known as a Fermi liquid parameter. (For a more detailed discussion of such effects, see Baym and Pethick (2004), Gross et al. (1991) and references therein.)

In practice, however, real systems do not possess translational invariance. Although the mass m_{CR}^* measured in a cyclotron resonance experiment does generally differ from that obtained from the de Haas-van Alphen effect (m^*), the simple expectations of Eq. (19) often do not hold; in one or two instances [see e.g., Rzepniewski et al., 2002], m_{CR}^* was even found to be greater than m^* . Nevertheless, a comparison between a cyclotron resonance experiment and the de Haas-van Alphen effect is often a good guide to the strength of the interactions in a system.

Effects related to cyclotron resonance

There are one or two effects related to cyclotron resonance that go beyond the scope of this article but which should nevertheless be mentioned for completeness. One is *surface cyclotron resonance*, an effect due to excitation of quasiparticles between levels caused by crossed electric and magnetic fields at the surface of a sample. Interested readers are referred to Koch and Jensen (1969) and Merkt (1985) and references therein. A second is the *Fermi-surface traversal resonance* due to the magnetic-field-induced motion of quasiparticles across open sections of Fermi surface; a discussion and relevant literature are given by Schrama et al. (2001).

Conclusion

Providing that a proper treatment of the sample's high-frequency magnetoconductivity is used, then the scattering rate τ_{CRM}^{-1} deduced from a cyclotron resonance experiment is a good measure of the energy width of the Landau levels due to their finite lifetime. In other words, $\tau_{\text{CRM}} \approx \tau_{\text{CR}}$. By contrast, the *apparent* scattering rate deduced from a simple-minded treatment of de Haas-van Alphen and Shubnikov-de Haas oscillations can contain significant contributions from spatial inhomogeneities. Finally, the scattering rate τ_{σ}^{-1} measured in a zero-field conductivity experiment can be very significantly different from τ_{CR}^{-1} because the two measurements are sensitive to different types of scattering process.

The scattering rates deduced from cyclotron resonance therefore provide the purest gauge of the Landau-level width. Once this has been realized, cyclotron resonance can be used to give quantitative details of the quasiparticle scattering mechanisms [e.g., Häussler and Welles, 1966; Vaughan et al., 1996; Post et al., 2021]. Cyclotron resonance is also an invaluable gauge of the importance of many-body effects [e.g., Rzepniewski et al., 2002]. Moreover, with the right choices of field and wavelength, cyclotron resonance can provide a measurement of the effective mass in systems where the scattering rate is too large for the de Haas-van Alphen or Shubnikov-de Haas oscillations to be visible [e.g., Post et al., 2021].

At present (2022), the combination of far-infrared optical equipment and high magnetic fields necessary for cyclotron resonance is relatively rare; examples tend to be concentrated at national high-field user facilities. Nevertheless, as new correlated-electron systems continue to be made, and as new approaches such as THz-TCDS become more widely used, the technique should have an important role in condensed-matter science for years to come.

Acknowledgments

Work at the National High Magnetic Field Laboratory on the high-frequency magnetoconductivity of metals is supported by National Science Foundation Cooperative Agreement No. DMR- 1644779, the Department of Energy (DOE) and the DOE BES program "Science at 100 T." Development of high-frequency techniques has been greatly aided by grant LDRD-ER 20200285. Oxford University is thanked for the provision of a visiting professorship that greatly facilitated some of the work described in this Chapter.

Abstract

This article covers the observation of cyclotron resonance (CR) in semiconductors and semiconductor heterostructures. The experimental techniques employed involve magnetic fields, far-infrared radiation sources, and (mostly) cryogens. The fields may be swept, static, pulsed or even destructive, while the radiation sources range from broadband Fourier-transform spectrometers and fs laser techniques to monochromatic or quasi-monochromatic electron tubes and molecular-gas- and free-electron lasers. A primary focus of this article is the extraction of the carrier effective mass from CR, and how the measured value is affected by magnetic field, carrier density, temperature, illumination, and details of the bandstructure. Resonant and nonresonant interactions with excitations such as longitudinal optic and homopolar phonons also affect the CR spectra, and descriptions will be given as to how the strength of these electron-phonon interactions can be inferred from the data. Finally, other effects that shift or alter the CR spectra, such as coupling to subbands in heterostructures, and spin splitting, will be described.

Key points

- To introduce Landau quantization and cyclotron resonance.
- To explain how these relate to salient details of the semiconductor systems studied.
- To describe the types of apparatus used to observe cyclotron resonance in these semiconductor systems.
- To give a brief description of the effective mass measured in cyclotron resonance, and how it is affected by many-body and other effects.
- To describe how bandstructure and coupling to excitations such as optic phonons lead to nonparabolicity; and how this is measured using cyclotron resonance.
- To give brief descriptions of other phenomena observed using cyclotron resonance, such as coupling to subbands in - reduced-dimensionality systems, spin splitting and resonant polaron coupling.

Preamble

Periods in human civilization are frequently classified by the materials used to make the most advanced and vital tools and weapons; hence, we have the Stone Age, Bronze Age, Iron Age, etc. Following the same reasoning, one might say that we are presently (2023) living in the Semiconductor Age (Orton, 2009). Very many manufactured items, ranging from toasters to cars, from light bulbs to smartphones, from laptops to cruise missiles (and so on), depend on electronic and opto-electronic devices based on semiconductors (Miller, 2022). It is therefore very important to be able to characterize semiconductor materials, in particular their bandstructure and the scattering processes that affect the electrons and holes (Landwehr and Rashba, 1991; Orton, 2009; Singleton, 2001). At the simplest level, this involves measuring the electron and hole effective masses and their mobilities. The masses describe the curvatures of the conduction and valence band extrema, and how fast the charge carriers can be accelerated; the mobilities parameterize how soon the accelerated carriers will be scattered (Singleton, 2001). Cyclotron resonance (CR) has played, and continues to play, an important role in determining these quantities in bulk (three-dimensional or 3D) and layered (two-dimensional (2D) or quasi 2D) semiconductors (Landwehr and Rashba, 1991; Goryca et al., 2019). However, CR is capable of giving much more, for example, information about the interactions of electrons with each other and the with host lattice.

This article reviews the basic mechanism of CR and describes how it may be observed experimentally. Subsequently, it discusses information that can be obtained from the CR position and linewidth. In particular, it addresses the issue of how the effective mass m_{CR}^* measured in CR relates to the band-edge value m_0^* and how energy-level crossings, polaron coupling, spin splitting, and collective interactions affect the CR spectrum.

Cyclotron resonance: Basic description

General considerations

In magnetic induction B , the electronic energies become quantized into Landau levels (LLs) with energies (Singleton, 2001, 2023)

$$E_l(B, k_{\parallel}) = \left(l + \frac{1}{2}\right) \hbar \omega_c \pm \frac{1}{2} g \mu_B B + E(k_{\parallel}). \quad (1)$$

Here, l is an integer, and

$$\omega_c = \frac{eB}{m_{\text{CR}}^*} \quad (2)$$

is the cyclotron (angular) frequency. The second and third terms in Eq. (1) are respectively the spin splitting, with g , the Landé g -factor, and $E(k_{\parallel})$, the energy of motion in the direction parallel to the applied B ; here, $k_{\parallel}$ is the wavevector quantum number parallel to B . Note that, just as in free space, the electron energy in the direction of B is unaffected; moreover, ω_c is the exact analog of the classical free-electron cyclotron frequency eB/m_e , but with the effective mass m_{CR}^* replacing m_e , the free-electron mass.

As described elsewhere (Landwehr and Rashba, 1991; Singleton, 2001, 2023; Yoshioka, 2002), Landau levels have a field-dependent degeneracy; hence, in a degenerate semiconductor system, the number of occupied LLs varies with B . This is parameterized by the *filling factor*, ν . However, care is needed, because the definition of ν depends on the system under study (and to a certain extent, the workers involved!); it may include spin and valley degeneracy. For example, a single, full LL might be labelled $\nu = 1$ in a bulk semiconductor (or metal) where the spin splitting is small compared to $\hbar \omega_c$; that is, the definition includes both spin-split halves of the LL (Singleton, 2023). By contrast, in a high-mobility GaAs heterojunction, where the spin splitting is very clearly resolved, a full LL would usually be indicated by $\nu = 2$; each spin-split half of the LL is counted separately (Yoshioka, 2002). In a Si MOSFET, where valley degeneracy is also present, the situation would be described as $\nu = 4$ (Landwehr and Rashba, 1991).

The cyclotron effective mass, m_{CR}^* , is an orbitally averaged effective mass (Singleton, 2001). Since the free carrier density in degenerate semiconductor systems is much smaller than the atomic density, the electron or hole states are only occupied close to the band extrema. Consequently, the Fermi surface(s) occupies/occupy only a small fraction of the Brillouin zone (Lax, 1958). Under these conditions, the Fermi-surface sections are roughly ellipsoidal so that m_{CR}^* can be simply related to the effective masses for linear motion (i.e., transport) in various directions (Lax, 1958; Singleton, 2001).

CR occurs when electrons are excited between adjacent LLs by absorbing a photon of energy $\hbar \omega = \hbar \omega_c$; the selection rule is thus $\Delta l = \pm 1$. Most of the examples in this Chapter involve degenerate semiconductors, where the optical transitions are between filled and empty, or partially filled and partially empty LLs in either the conduction or the valence band. Nondegenerate semiconductors are also studied by CR; LLs in both conduction and valence bands are populated using cross-bandgap radiation. The latter situation is also described briefly below.

Most CR experiments are conducted in the Faraday geometry, where the direction of propagation of the radiation is parallel to B . Hence, the oscillating electric and magnetic fields are polarized in the plane perpendicular to the static magnetic field (Landwehr and Rashba, 1991). Another consequence of the relatively low free carrier density in degenerate semiconductors is that the skin depth is large;

almost the same oscillating electric field will be present throughout the sample (Singleton, 2023). Hence, the radiation couples to the center of mass motion of the electrons or holes and is insensitive to carrier-carrier interactions, a proposition known as *Kohn's theorem*.

As mentioned above, the CR transition has the selection rule $\Delta l = \pm 1$, which accounts for the unit of angular momentum absorbed from the photon; it is also spin preserving, and, because of the tiny photon momentum, does not alter $k_{||}$. Semiclassically, electrons and holes will perform cyclotron orbits in opposite directions, and this suggests a way to distinguish between them using circularly polarized radiation. Conduction-band electrons are excited to higher LLs by σ^+ circularly polarized radiation (this is termed *electron-active*;) hole CR will generally only be excited by oppositely handed σ^- circularly polarized light, though σ^+ may excite transitions between heavy and light hole levels in the valence band (Landwehr and Rashba, 1991).

Scattering of the charge carriers means that the LLs are broadened; this is reflected in the CR linewidth, which can be used as a quantitative measure of the sample quality (Singleton, 2023). If the average carrier scattering rate is τ^{-1} , then a well-resolved CR is likely to be observable if $\omega_c \tau \gtrsim 1$, a condition can be interpreted semiclassically as an average carrier completing at least one cyclotron orbit before scattering (Landwehr and Rashba, 1991; Singleton, 2001). The mobility μ is expressed as $\mu = e\tau/m^*$, allowing for the differences between m^* (the effective mass for linear motion) and m_{CR}^* (an orbitally averaged effective mass), the magnetic field needed for clear observation of CR can be written as $B \gtrsim \frac{1}{\mu}$. For example, for a carrier mobility of $\mu = 10^3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, $B \gtrsim 10 \text{ T}$ to observe a clear CR. (Conditions affecting CR linewidth are described in more detail in a companion chapter (Singleton, 2023).)

These limitations due to scattering rate mean that CR in semiconductors is normally measured at low temperature (4.2 K or less), where the mobility is highest. Similarly, CR in low-mobility semiconductors is only recorded using the highest available magnetic fields (Puhlmann et al., 1998).

Further broadening of the CR line can arise from dielectric mismatch, especially within layered structures and at frequencies close to poles in the dielectric response (Langerak et al., 1988). In some cases, this can completely mask the effects of broadening due to scattering and even change the line from the clean Lorentzian of Fig. 1 to a differential shape, from which it is much more difficult to extract the true resonance position. This effect can often be corrected for by modeling the dielectric response of the particular sample being investigated (Langerak et al., 1988).

Magnetoplasmon modes

The former description of CR as a resonant absorption is completely adequate in most cases, but is an oversimplification. The CR absorption spectrum can be calculated within linear response theory as being proportional to the real part of the dynamical conductivity (Kushwaha, 2001). As we will see below, CR is generally studied using far-infrared (FIR) radiation. Such illumination causes a long-wavelength perturbation of the electron plasma, which has a collective response. In a magnetic field, the plasma excitation modes occur close to integer multiples of ω_c . The lowest of these is referred to as the magnetoplasmon mode, and at small wave vector k , is equivalent to forming a magnetic exciton comprising the excited electron in the upper LL and the hole remaining in the lower LL. The excitation has an energy $E(k) = \hbar\omega_c + \delta E(k)$, where the second term represents the magnetoexciton binding energy due to electron correlations (Kushwaha, 2001). Pure CR corresponds to the $k \rightarrow 0$ limit of the magnetoplasmon, in which limit $\delta E(k) \rightarrow 0$ as a consequence of Kohn's theorem (Singleton, 2023).

Band nonparabolicity reflects the fact that the semiconductor is not truly translationally invariant, but is made up of discrete atoms. More obviously, translational invariance is broken by lattice defects, impurities, and the interfaces and composition variations in heterostructures and other 2D systems. Consequently, $k \neq 0$ modes may be allowed to mix with the pure CR mode at $k = 0$. Coupling to other plasmon modes of the electron gas is then possible, especially when a metallic grating is applied to the surface of the semiconductor in order to impose spatial periodicity on the FIR excitation and thereby select particular wave vectors (Kushwaha, 2001).

Experimental techniques

The CR condition for a particular specimen can be satisfied either by applying monochromatic radiation of a fixed frequency and varying the magnetic field, or by fixing the field and varying the radiation frequency (Landwehr and Rashba, 1991; Singleton, 2023).

Swept field, fixed frequency

Quasistatic magnetic fields of up to $B = 45\text{ T}$ are generated in resistive and hybrid magnets provided at national user facilities (see the webpages of the various national magnet laboratories for up-to-date information on maximum fields). On a smaller scale, commercial superconducting magnets can provide $B \approx 17 - 21\text{ T}$, though the advent of reliable cuprate superconductor tape promises higher fields in the near future. At the other extreme, nondestructive pulsed-field magnets can give $B \approx 100\text{ T}$; as we shall see below, even higher fields are possible in destructive pulsed magnets (Puhlmann et al., 1998). All of these different ways of providing swept magnetic fields have been used with monochromatic FIR to observe CR in semiconductors.

Typical semiconductor electron and hole masses lie in the range $0.01 \lesssim m_{\text{CR}}^*/m_e \lesssim 1$ (Landwehr and Rashba, 1991). Taken with the above routinely accessible fields of $B \sim 10\text{ T}$, this means that FIR sources with wavelengths $10 \lesssim \lambda \lesssim 1000\text{ }\mu\text{m}$ are required. Suitable monochromatic FIR can be obtained from a molecular gas laser pumped by a CO_2 laser operating at $9\text{--}11\text{ }\mu\text{m}$ (Jacobsson, 1989); typical lasing media are low-pressure vapors of methanol, formic acid, etc. or their deuterated variants. Though hundreds of lines can be obtained from such optically pumped FIR lasers, many experiments are limited to around 20 strong lines (Langerak et al., 1988), with $118.8\text{ }\mu\text{m}$ being one of the most popular. Owing to strong atmospheric absorption of many of these FIR lines, radiation is usually conveyed from the laser to the magnet cryostat assembly using evacuated, cylindrical brass light pipes. Transmitted FIR is frequently detected by a carbon or Ge bolometer in the cryostat with the sample; noise is reduced using a lock-in amplifier synchronized with mechanical chopping of the laser (Langerak et al., 1988). Interference due to internal reflections from the back and front surfaces of the sample can result in distorted CR line shapes; to prevent this, samples are usually wedged by a few degrees (Langerak et al., 1988; Michels et al., 1996). The stability of the laser output over the course of the sweep of the magnetic field can be an issue, but this is ameliorated by taking the ratio of signals from the transmission bolometer and one that records the incident radiation. It is also possible to detect the CR through changes in the resistance of the sample being investigated in a photoconductivity measurement. Measurements at high fields can also be made in the “quantum limit,” where only one LL is initially populated, as opposed to the classical limit at low fields. Between these limits, studies have been made of the effect of filling factor ν on the line width, which can oscillate with the density of available initial and final states (Landwehr and Rashba, 1991).

Very high (megagauss) and very low fields

At pulsed magnetic fields in the megagauss regime ($B \sim 100\text{ T}$), the more powerful CO_2 laser can be used directly; other possible sources include H_2O , CO , and HeNe lasers. At these shorter wavelengths, fast (Hg,Cd)Te photovoltaic detectors can be used to detect the rapid change in IR intensity. Magnetic fields of up to 180 T are produced using the single-turn-coil technique pioneered at ISSP Tokyo (Puhlmann et al., 1998; Cole et al., 1997). A low-inductance capacitor bank is discharged through the coil to give currents of order 2 MA for $\approx 7\text{ }\mu\text{s}$. The maximum field is set by the capacitance and voltage of the bank and the coil diameter, which is typically about 10 mm . Though the coil explodes violently outwards, the cryostat and sample are (mostly!) left intact and the experiment can be repeated. Data from the detector and a pickup coil are transmitted via optical fiber to a shielded room where they are recorded on a fast multichannel digitizer. The pick-up voltage allows the field to be calibrated each time to an accuracy better than 2% . A set of typical CR recordings are shown for several II–VI semiconductors in Fig. 2.

Even higher fields, beyond 600 T , can be obtained using the electromagnetic flux-compression technique (Puhlmann et al., 1998). A pulsed current through an outer primary coil seeds a magnetic field and induces an opposing secondary current within an inner copper ring. The repulsive forces generated rapidly squeeze the ring, causing it to implode and compress the trapped magnetic flux density to a very high value. Unfortunately, the entire cryostat and sample are destroyed in this one-shot experiment! However, the extreme fields mean that CR can be studied in materials with large scattering rates, such as the dilute magnetic semiconductor $\text{In}_{1-x}\text{Mn}_x\text{As}$, where heavy doping with magnetic impurities reduces the mobility. Data are shown in Fig. 2 for a temperature-dependent study of CR in CdS (Imanaka et al., 1998). Notice that at room temperature the CR peak is over 100 T wide.

By contrast, CR has also been observed at very low fields (20 mT), in very high quality $\text{GaAs}/(\text{Ga},\text{Al})\text{As}$ heterojunctions where the mobility exceeds $10^6\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$ using microwave radiation from 17 to 90 GHz Gunn diodes. At these low fields, the cyclotron radius is $\sim 2\text{ }\mu\text{m}$, which enables potential fluctuations in the sample to be observed on this macroscopic scale.

Fourier transform spectroscopy

The advent of reliable high-field superconducting magnets and Fourier transform infrared (FTIR) spectrometers in the late 1980s has provided a useful alternative to the swept-field CR measurements. In this technique, the FIR source is a mercury vapor lamp, heated metal wire or globar producing a broad spectrum of radiation. The radiation is sent through a Michelson interferometer before passing through the sample and being detected by a cooled Si bolometer. By rapidly scanning the moving mirror in the interferometer and recording the FIR intensity as a function of its position, an interferogram is produced. This is then fast-Fourier

transformed to yield a transmission spectrum with a resolution of $\sim 0.1 \text{ cm}^{-1}$ ($\sim 0.01 \text{ meV}$). Each scan only takes a fraction of a second, but can be repeated many times to increase the signal-to-noise ratio. Intensity variation in the source spectrum and detector response can be removed by taking the ratio of spectra with and without the sample present. In practice, a set of transmission spectra are usually recorded as the magnetic field is stepped through the range of interest (Fig. 3) and differences are detected from the ratio of adjacent spectra. As a result of FTIR spectroscopy, the CR can be followed continuously as a function of magnetic field or energy, which allows detailed measurements of band nonparabolicity and subband structure to be made (Michels et al., 1995).

Terahertz time-domain spectroscopy

As an alternative to the continuous wave (CW) optical methods described in the previous sections, ultrafast pulsed lasers are used to generate and detect broadband pulses of THz radiation (Baydin et al., 2021). THz time-domain spectroscopy (THz-TDS) techniques have been combined with both constant and pulsed magnetic fields to observe CR in semiconductors.

Methods to generate THz radiation include using the output beam of an ultrafast laser to induce optical rectification in a nonlinear crystal such as ZnTe, GaSe, or LiNbO₃. Photoconductive antennas can also be employed; here the ultrafast laser pulse excites carriers in a material such as low-temperature grown GaAs. These carriers are then accelerated by a bias voltage, leading to a short current pulse $\sim 1 \text{ ps}$ that generates electromagnetic radiation in the THz frequency range.

Depending upon the method of generation and the pulse duration of the original ultrafast laser pulse, THz radiation in the frequency range 0.1–100 THz is generated. Detection methods include free space electro-optic sampling based on the Pockels effect, where the electric field of a THz pulse induces birefringence in a nonlinear crystal such as ZnTe. By analyzing the polarization of a detection pulse through the nonlinear crystal, the amplitude and phase of the THz electric field can be determined at a particular time. The THz electric field can then be mapped out as a function of time by varying the time delay between the detection pulse and the THz pulse; normally this is accomplished via mirrors on a mechanical translation stage.

THz-TDS allows for the direct measurement of both the amplitude and phase of the THz electric field as opposed to other techniques that only measure the intensity of radiation. The simultaneous direct measurement of both the amplitude and phase of the THz electric field transmitted through a sample allows one to determine both the real and imaginary part of the frequency-dependent conductivity without using techniques involving the Kramers–Kronig relations. Because THz-TDS techniques generally

utilize lasers that operate in the near-infrared range, it is also possible to optically pump carriers across the bandgap of semiconducting samples before the THz pulse arrives in an optical pump/THz probe experiment.

Fig. 4 shows an experimental set-up in which a direct current (DC) superconducting magnet is incorporated into the free-space beam path of a THz-TDS spectrometer (Baydin et al., 2021). The field is applied parallel to the light propagation direction (i.e., the Faraday geometry). CR in a high-mobility two-dimensional electron gas (2DEG) in GaAs has been measured using THz-TDS to determine the cyclotron coherence time directly, without the need for lineshape analysis and bypassing the saturation effect where

the linewidth measured by FTIR is larger than the true linewidth (Wang et al., 2010). By subtracting the THz electric field that is transmitted through a 2DEG sample at 0 T from the transmitted THz radiation at finite B , one is left with an exponentially damped sinusoidal wave,

$$E(t) = A \exp(-t/\tau_{\text{CR}}) \sin(\omega_c t + \theta_0), \quad (3)$$

where A is the electric field amplitude, τ_{CR} is the CR decay time, ω_c is the CR angular frequency, and θ_0 is the starting phase of the oscillation. Fig. 5 shows CR oscillations in a high-mobility 2DEG in GaAs at various applied magnetic field strengths. Furthermore, it was discovered that in such a 2DEG system, the CR decay rate increased linearly with electron density, illuminating the role of many-body effects in CR decoherence via superradiant damping (Zhang et al., 2014).

Recently, THz-TDS studies in topological insulator $\text{Pb}_{0.5}\text{Sn}_{0.5}\text{Te}$ have revealed two types of carriers which display different CR dispersions, helping to further understand bulk states in Dirac and Weyl semimetals (Cheng et al., 2019).

In order to perform THz-TDS in pulsed magnetic fields, one must vary the time delay between the THz pulse and the detection pulse much faster than can be achieved with a mechanical delay stage. Two THz-TDS methods have been demonstrated to measure CR in pulsed magnetic fields. Electronically controlled optical sampling (ECOPS) utilizes two ultrafast lasers with nominally identical repetition rates (inverse of the time between consecutive pulses), except that one of the lasers (the “slave”) incorporates a piezo-electric crystal to electronically modify the laser cavity length and hence repetition rate. By sweeping the repetition rate of the ‘slave’ laser in a close range around the fixed repetition rate of the ‘master’ laser, one can generate a set of two pulses at electronically controllable time delays with respect to each other. One is used to generate THz radiation, and the other is used for detection. ECOPS THz-TDS systems can be used to measure a THz waveform within a time window ~ 10 s μ s, which is suitable for use with pulsed magnets whose magnetic field strength varies on ms timescales. This method has been employed to measure CR in a high-mobility 2DEG in GaAs using a mini-coil pulsed magnet (Noe et al., 2014).

Single-shot THz-TDS techniques utilize a single laser where time delay information is encoded across the intensity profile of the detection pulse that is used to measure the THz radiation. The time delay information can be encoded by reflecting the detection pulse off of an echelon mirror. Different portions of the detection pulse will arrive at the detection crystal at slightly different times. The intensity profile of the detection pulse is finally imaged onto a two-dimensional camera providing a space-to-time mapping of the THz electric field. The measurement time is identical to the time delay range of the THz electric field measurement (~ 10 s ps) meaning this technique is suitable for magnetic field pulses of any duration presently used for high magnetic field research. In an intrinsic Si sample, CR has been measured by single-shot THz-TDS after optically pumping carriers across the Si band gap in magnetic fields of up to 30 T (Noe et al., 2016).

Free-electron lasers

The limitation of the restricted number of lines from an optically pumped FIR laser can also be overcome by using a FIR free-electron laser (FEL) as a source for CR (Langerak et al., 1998a, b; Van Bockstal et al., 1998). FELs consist of an electron accelerator, an

Fig. 6 Picosecond time-resolved CR in InSb using micro-pulses from an FEL. Initially, the very high density of photocreated electrons produces a very wide CR due to carrier scattering; only after ~ 1 ns is equilibrium restored. undulator in which the electrons emit radiation, and an optical resonator. By adjusting the undulator and electron energy, the output can be tuned over a rather large range (a factor ~ 3 – 20 in frequency); without changing the accelerator energy, the FIR frequency can be scanned over a factor ~ 2 . Most FEL systems are driven by repetitively pulsed electron accelerators, and the resulting electron bunch structure (often a train of picosecond-duration micropulses within a 0.01 – 5 μ s macropulse that is repeated at ~ 10 Hz) may be useful in time-resolved experiments (Fig. 6) (Kono et al., 1999). Over the past two decades, FELs have been colocated with high-magnetic-field facilities (Ramian, 2022) with such experiments in mind.

Optically detected cyclotron resonance

Rather than monitoring the FIR absorption directly, optically detected cyclotron resonance (ODCR) detects the variation in photoluminescence (PL), excited by a laser pumping electrons across the bandgap, due to FIR illumination (Michels et al., 1994). ODCR has some useful benefits: (i) undoped samples can be studied since the pump laser provides carriers; (ii) the conduction and valence band can be studied simultaneously; and (iii) the CCD arrays or photomultiplier tubes that are used to detect PL offer great sensitivity. ODCR is detected using the response of the PL intensity to chopped FIR; the signal is recorded either as the magnetic field is swept or the PL energy varied at fixed field. ODCR is clearly only suited to direct bandgap semiconductors that have a strong PL signal.

ODCR studies in bulk GaAs show the free-electron CR and also reveal transitions from the ground to excited states of donor-bound impurities (Fig. 7). Chemical shifts due to different donor atoms also appear with improved resolution compared to photoconductivity measurements. It is thought that the FIR illumination liberates electrons from donor sites to the conduction band, increasing the impact ionization of bound excitons and thus reducing the PL signal, which is predominantly due to excitonic recombination. The free electron luminescence makes a much smaller contribution to the PL. In magnetic field, charged excitons (or trions—labeled X^-) also have an energy quantized into a set of LLs, and CR between these can be used to extract the trion effective mass and lifetime (Michels et al., 1994).

In quantum wells, the ODCR signal is strongly dependent on the filling factor and, when the cyclotron energy exceeds the inter-subband separation, can show a complete transfer of luminescence intensity from the ground to second subband at resonance.

A development of ODCR is far-infra-red-modulated photoluminescence (FIRM-PL) whereby the whole PL spectrum is recorded at a fixed magnetic field, by dispersing the luminescence signal onto a CCD with typically a 1 m spectrometer (Chang and Nicholas, 1999). Two series of such spectra are taken as the magnetic field is stepped, with and without FIR radiation, and the CR contribution to each of the PL lines can be seen in their difference (Fig. 8). By studying these differences, as functions of magnetic field, PL, and

FIR power, much can be learned about the energy levels and carrier dynamics within the semiconductor. However, such data must be interpreted carefully to account for the changes in carrier distribution and increases in nonradiative recombination due to FIR heating.

Effective mass measurements

Measurable features of a CR include the peak position, intensity, and linewidth. The integrated intensity of a CR line can be used to obtain the density of carriers responsible for the absorption, and the line width (after suitable correction) gives a measure of their mobility. The CR position is primarily used to extract the effective mass, m_{CR}^* (see Eqs. 1 and 2), which is often a function of the field orientation and the FIR energy (Lax, 1958; Landwehr and Rashba, 1991; Singleton, 2001).

Field-orientation dependence of the cyclotron effective mass

Although a spherically symmetric effective mass is a reasonable approximation for the conduction band minima of materials such as GaAs and InSb (Singleton, 2001), the bands in many semiconductors are much more anisotropic. In such cases, the effective mass is expressed as an inverse-mass tensor (Landwehr and Rashba, 1991; Singleton, 2001)

$$\left(\frac{1}{m^*}\right)_{ij} = \frac{1}{\hbar^2} \left(\frac{\partial^2 E}{\partial k_i \partial k_j} \right), \quad (4)$$

where k_i and k_j are components of the wavevector quantum number $\mathbf{k}$. CR measures an average of the effective mass about a cyclotron orbit perpendicular to the applied magnetic field. Hence, by rotating the sample to different angles with respect to the magnetic field, and recording the CR spectra, the anisotropy can be mapped out. Practically, the rotation axis is perpendicular to the applied magnetic field, and usually chosen to be a one of the three principal crystalline axes. Frequently the experiment will be performed for two different planes of rotation. A pioneering example of this technique applied to Ge and Si (Dresselhaus et al., 1955) is shown in Fig. 9. Such data were instrumental in working out the bandstructures of these technologically important elements, and CR continues to be used to characterize new materials in a similar manner (Landwehr and Rashba, 1991; Goryca et al., 2019).

Fig. 9 Effective mass of electrons in Ge measured by CR for different crystalline directions. Solid lines are calculations. Permission from Dresselhaus G, Kip AF, and Kittel C (1955) Cyclotron resonance of electrons and holes in silicon and germanium crystals. *Physics Review* 98: 368

The anisotropy can become very large in reduced-dimensionality semiconductor systems such as semiconductor heterostructures and monolayers containing 2DEGs. Sometimes the confinement leads to almost perfect two-dimensional behavior of the CR, with the effective mass increasing as $1/\cos\theta$ as the field is tilted by an angle θ away from the normal to the layers. In other systems, the incorporation of strain into pseudomorphic layers, for example in $\text{Si-Si}_{1-x}\text{Ge}_x$ or $\text{GaAs-In}_x\text{Ga}_{1-x}\text{As}$ (Landwehr and Rashba, 1991), produces a more complex anisotropy, especially in the valence band where heavy and light hole bands show considerable mixing. Hence, CR has been used as a valuable tool for checking bandstructure calculations, especially for p-type quantum wells (Cole et al., 1997).

Nonparabolicity from bandstructure

An energy-independent effective mass requires a perfectly parabolic band; in other words, one in which $E \propto k^2$. In real solids, however, bands have a finite energy width, and therefore both maxima and minima; between these, the electron dispersion relationship *must* inevitably deviate from parabolicity and the effective mass becomes a function of energy (Singleton, 2001).

However, most semiconductor applications involve electrons in states near to the band extrema, and some simplifying approximations can be made. First, at energies very close to the band extrema, the electronic dispersion relationship can frequently be approximated as a parabola. Then, at slightly higher energies, the nonparabolicity can in many cases be treated as a perturbation. For example, for the energies typically used in CR ($h\nu \lesssim 30$ meV), the nonparabolicity of the conduction band of many direct-gap semiconductors (such as InSb and GaAs) can be parameterized using the following expression (Hopkins et al., 1987; Peeters, 2004), derived using five-band **k.p** theory:

$$m_{\text{CR}}^* = m_0 \left\{ 1 + \frac{2K_2}{E_g} ([l+1]\hbar\omega_c + \langle T_z \rangle) \right\}. \quad (5)$$

Here, $\langle T_z \rangle$ is the kinetic energy parallel to the magnetic field, l is the initial Landau-level quantum number, E_g is the bandgap and K_2 parameterizes the nonparabolicity. K_2 is usually negative, so that m_{CR}^* increases with energy. This increase is observed (Fig. 10) by changing the FIR frequency; when the CR transition occurs at higher field, ω_c is greater and the final state is higher in the band. Similarly, in high-mobility systems, transitions between different LLs may be resolved as distinct lines with for example, the $l = 1 - 2$ transition occurring at a higher field than the $l = 0 - 1$.

Nonparabolicity may also result in an effective mass that is a function of carrier density; as the Fermi energy increases, the initial LL quantum number l of the CR transition moves to progressively higher values (and thus higher m_{CR}^*), a phenomenon known as the Moss-Burnstein effect (Hopkins et al., 1987; Landwehr and Rashba, 1991). The observed mass may also increase with temperature. Two mechanisms are involved here; electrons are thermally excited to higher LLs and thermal motion contributes to an increased $\langle T_z \rangle$. Another important contribution to $\langle T_z \rangle$ is the confinement energy in heterostructures, which generally results in 2D systems having larger m_{CR}^* than the corresponding bulk semiconductor in otherwise identical CR experiments.

Fig. 10 Energy dependence of m_{CR}^* in 3D and 2D GaAs, showing the bandstructure and polaron contributions to nonparabolicity. The 3D results are shifted up by 0.0012 for comparison. New Jersey: World Scientific; Langerak CJGM, Singleton J, van der Wel PJ, Perenboom JAAJ, Barnes DJ, Nicholas RJ, Hopkins MA, Foxon CTB (1988) Carrier-concentration-dependent electron-LO-phonon coupling observed in GaAs-(Ga, Al)As heterojunctions by resonant-polaron cyclotron resonance. *Physical Review B* 38: 13133

Nonparabolicity due to polaron coupling

In polar semiconductors, there is an additional contribution to the nonparabolicity from polaron coupling (Fig. 10), which may be of similar magnitude to that due to the band structure (Devreese, 2007; Devreese and Alexandrov, 2009; Langerak et al., 1988; Peeters, 2004). When an electron or hole moves through a polar solid, it attracts or repels the charged ions around it; the associated strain field accompanying the carrier affects its self-energy and effective mass. The composite quasiparticle is known as a *polaron*, and may be regarded as a carrier dressed by virtual longitudinal optic (LO) phonons. We will see below that as the carrier energy approaches the LO phonon energy, $\hbar\omega_{\text{LO}}$, the coupling becomes resonant, producing a strong effect on the Landau levels.

However, at carrier energies $\ll \hbar\omega_{\text{LO}}$, the polaron has an effective mass m_λ^* that is larger than that expected from the underlying bandstructure (m^*) (Devreese, 2007; Devreese and Alexandrov, 2009; Langerak et al., 1988; Peeters, 2004),

$$m_\lambda^* = m^* \left(1 + \frac{\alpha}{6} \right), \quad (6)$$

where α is the Fröhlich coupling constant; for example, $\alpha = 0.07$ in GaAs and 1.2 in ZnO. In addition, the nonparabolicity is increased by an amount

$$\Delta K_{2,\text{pol}} = -\frac{3\alpha E_g}{40\hbar\omega_{\text{LO}}}. \quad (7)$$

This explains the apparent discrepancy between the calculated $K_2 = -1.4$ in GaAs, expected from the bandstructure, with the actual value $K_2 = -1.8$ observed in CR measurements of low-electron-density samples (Fig. 10).

While the above mass and nonparabolicity enhancements are clearly observed in bulk semiconductors, they can be screened out in a degenerate 2DEG at low temperatures, reappearing at higher temperatures once the screening becomes less efficient (Fig. 11).

Polaron coupling becomes especially important as $\omega_c \rightarrow \omega_{\text{LO}}$; anticrossing occurs between the second LL and first LL plus an LO phonon (Fig. 12), opening an energy gap and bending the energy levels (Devreese, 2007; Devreese and Alexandrov, 2009; Langerak et al., 1988; Peeters, 2004). The two branches of the upper level can be traced out using CR at energies above and below the reststrahlen band; however, close to this region, careful interpretation of the CR lineshape is required to account for internal reflections, especially in layered heterostructures (Langerak et al., 1988; Singleton, 2023). In addition to resonant polaron coupling to LO phonons, a similar but weaker effect is observed in layered semiconductors due to homopolar optic phonons that modulate the layer thickness and couple to the carriers via a deformation potential (Howell et al., 1989).

Besides changing the CR energy, electron-phonon scattering can affect the CR linewidth. Inter-Landau level transitions may occur via phonon absorption/emission when $\omega_{\text{LO}} = j\omega_c$, where j is an integer. This effect is known as magnetophonon resonance (MPR), and is visible in semiconductors such as GaAs at temperatures of 80–200 K, where there is a favorable balance between LL width and optic phonon population. MPR is usually observed in transport measurements, but may also be seen as a modulation of the CR linewidth (Brummell et al., 1988).

Shifts and coupling of the resonance

We have already seen that the CR position can be altered by electron-phonon interactions. This section discusses some other mechanisms that may move and broaden CR spectra.

Fig. 11 Comparison of the temperature dependence of m_{CR}^* in 3D and 2D GaAs. Temperature-dependent screening of the polaron CR contribution in 2D is seen in the difference between the dashed extrapolation from high temperature and the data. Note the increase due to confinement in 2D. Subband structure

Reduced-dimensionality systems such as heterojunctions and quantum wells may have several electric subbands, due to confinement. Transitions between LLs of different subbands are usually forbidden, but the presence of a magnetic field component in the 2D plane mixes these states, permitting resonant subband-Landau-level coupling (RSLC) between, for instance, the $l = 1$ LL of the lowest E_0 subband and the $l = 0$ LL of the next E_1 subband. Thus, subband energies can be detected in tilted field CR as a discontinuity in m_{CR} as a function of energy or field, accompanied by an increase in CR linewidth at the RSLC condition (Fig. 3). This method has been used to determine the energy levels for a wide variety of structures, including heterojunctions, quantum wells, and superlattices (see e.g., Landwehr and Rashba, 1991; Michels et al., 1994; Winkler, 1996; Zawadzki and Pfeffer, 2004). In high-quality samples, the CR splits to reveal transitions to the upper and lower branches, and shows a transfer of oscillator strength from one to the other on passing through the resonance. In contrast to direct inter-subband transitions, which require the light to be polarized perpendicular to the interface and which exhibit a significant depolarization shift, in CR, the light is polarized parallel to the interface (even in tilted fields due to the high dielectric constant of most semiconductors) and depolarization shifts are very small.

Frequency-shifted CR

If carriers are bound to a harmonic potential Δ , then the CR angular frequency can be shifted from ω_c to ω

$$(\hbar\omega)^2 = (\hbar\omega_c)^2 + \Delta^2. \quad (8)$$

This occurs in for example, n -ZnO and n -CdS, where electrons may become bound in shallow traps (i.e., not bound impurity states). The effect has also been seen in quantum wells, where fluctuations in well width lead to carriers being confined to islands of lower potential (Merkel, 1996). For shifted CR to be observed, the localization length needs to be greater than the cyclotron radius, but not so large that the perturbation is the same for the initial and final state.

Landau level hybridization

An interesting example of LL hybridization occurs in heterojunctions in which the conduction band minimum in one semiconductor is below the valence band maximum in the other (i.e., InAs-GaSb heterojunctions). This leads to a semimetallic system with

spatially separated electron and hole gases, unless the structure contains narrow quantum wells, where the additional confinement uncrosses the energy gap to produce a semiconducting arrangement (Singleton, 2001).

In the semimetallic examples, CR can be observed between both electron and hole LLs, and by following their position as a function of magnetic field, the relevant band-edge energies can be found. Strong oscillations of the CR linewidth and amplitude have been also observed; these disappear when the electron and hole layers are separated by a thin barrier. Maxima in linewidth occur whenever electron LLs and hole LLs cross, at which point energy gaps arise from hybridization of the electron and hole LLs. The hybridization only happens when the electron and hole wave functions can overlap by tunneling through the interface; this is why a thin barrier suppresses the effect (Warburton et al., 1996 and references therein). Similar hybridization phenomena have been seen in coupled GaAs quantum wells that form symmetric and antisymmetric wave functions.

Spin splitting

Eq. (1) shows that there are separate LL fans for each spin state. In a nonparabolic band, the spin-preserving CR transitions will be at different energies for spin-up and spin-down carriers, enabling the g -factor to be measured. As has been discussed elsewhere (Singleton, 2023), FIR-induced transitions are in general not sensitive to electron-electron interactions in a homogeneous layer (Kohn's theorem), so the g -factor measured in CR gives the single-particle value, and not the enhanced value detected in transport measurements.

The g -factor splitting is small in wide-gap materials (Zawadzki and Pfeffer, 2004), such as GaAs ($g = 0.44$), and spin-split CR is only observed in the quantum limit (see below). However, spin split CR is readily seen in narrow-gap semiconductors, such as InSb (Fig. 13), where the proximity of conduction and valence bands leads to strong nonparabolicity as well as a large g -factor (Khodaparast et al., 2004a). For InAs, with $g = -15$, the spin energy gap is so large that at low electron density and temperature, only the lower spin state is populated and only one CR line is observed, but once the second spin level becomes populated at higher temperature (or density), the second line appears. The onset of the second line can be used as a measure of carrier density (Landwehr and Rashba, 1991).

Dilute magnetic semiconductors, such as $\text{In}_{1-x}\text{Mn}_x\text{As}$, have ferromagnetic phases below ≈ 50 K. The ferromagnetic exchange between Mn ions is believed to be hole mediated, and strongly affects both the conduction and valence band parameters due to the narrow bandgap. Megagauss hole CR, in Fig. 14, shows lines that shift to lower fields and intensify as the ferromagnetic phase is

Fig. 14 CR spectra at 10.6 μm from a InMnAs/GaSb heterojunction in magnetic fields of up to 150 T. On cooling through the ferromagnetic transition at 55 K, an additional line appears. Permission from Khodaparast GA, Kono J, Matsuda YH, Ikeda S, Miura N, Wang YJ, Slupinski T, Oiwa A, Munekata H, Sun Y, Kyrychenko FV, Sanders GD, and Stanton CJ (2004b) High-field cyclotron resonance studies of InMnAs-based ferromagnetic semiconductor heterostructures. *Physica E: Low-Dimensional Systems and Nanostructures* 21: 978–982

entered, consistent with the additional Mn exchange field increasing the spin splitting. In this regime, $\mathbf{k}\cdot\mathbf{p}$ calculations show that the spin splitting depends on temperature, magnetic field, and Mn concentration leading to a g -factor that varies from -20 to $+100$ (Khodaparast et al., 2004b). CR experiments proved vital in validating and refining such calculations.

Though spin-split electron CR is commonly observed in bulk GaAs (Mayer and Rössler, 1991), it has only been seen in 2DEGs at very low electron filling factors ($\nu < 10$) (Michels et al., 1996). At this very low filling factor and 100 mK, only the lowest transition occurs close to the position expected in bulk GaAs. On warming, the upper spin level becomes thermally populated and two lines appear by 1 K, with their relative intensities in accord with Boltzmann statistics based on the spin splitting expected in a single-particle picture. For $\frac{1}{10} \leq \nu \leq \frac{1}{6}$, this regime starts to break down, revealing a smaller splitting than expected. Finally, for $\frac{1}{6} \leq \nu \leq 2$, one CR line is seen that shifts from the position of the lower spin transition by up to half the spin splitting as the temperature increases. These results have been explained by a model whereby the cyclotron motions of the two spin states are coupled by the Coulomb interaction, which depends on the total electron density. The CR spectrum reflects hybridized spin-up/spin-down states, with the position of the single peak determined by the relative spin population (Cooper and Chalker, 1994).

A similar situation arises in Si, where two- and fourfold degenerate valleys possess different effective masses. Again, only a single CR line is observed until the system is considerably perturbed by uniaxial stress. Attempts to explain this rely on electron–electron interactions coupling the single-particle states (Landwehr and Rashba, 1991; see also Cole et al., 1997, and references therein).

Fractional quantum Hall effect

Throughout the temperature and field regime where fractional quantum Hall effect (FQHE) features are seen in transport experiments on GaAs-(Ga,Al)As heterojunctions (Yoshioka, 2002), there are no detectable deviations of the CR mass or line width, showing that CR is not affected by the electron correlations responsible for the FQHE (Michels et al., 1996).

Magneto-excitons vs. cyclotron resonance

An exciton is a bound electron-hole pair that can be created when a photon of energy greater than the bandgap of a semiconductor is absorbed (Singleton, 2001). Upon absorption of the photon, an electron is promoted from the valence band into the conduction band and a positively charged hole is left behind. The electron and hole can be bound via the Coulomb interaction. An exciton is

analogous to the hydrogen atom, but it has a smaller binding energy due to the smaller reduced mass of the exciton and screening due to the dielectric environment of the lattice (Singleton, 2001).

Excitons have a series of bound states which modify the optical response near the band edge of semiconductors. These can be readily observed via absorption measurements when the binding energy is greater than the thermal energy. An applied magnetic field will modify the energy of the exciton. In the low magnetic field limit, the energy of the magneto-excitons shows a diamagnetic shift and Zeeman splitting similar to that of the hydrogen atom. In the high magnetic field limit, however, the effect of the magnetic field will dominate, and the magneto-exciton energies show a linear magnetic field dependence similar to the LLs of free electron-hole pairs.

The quantitative evolution of the exciton energy dependence on magnetic field depends on basic parameters of the exciton such as the binding energy, reduced mass, Bohr radius, and g-factor; therefore, analyzing the absorption spectra of semiconductors as a function of applied magnetic field can provide valuable information about the basic properties of excitons in semiconductors (Singleton, 2001). This has been extensively achieved over many decades for traditional III-V and II-VI semiconductors in both bulk samples and quasi-2D heterostructures. Recently, after advances in the synthesis of monolayer transition-metal dichalcogenide (TMD) semiconductors, magneto-optical measurements have been used to determine the basic excitonic properties including the exciton mass, size, and binding energy for these novel materials (Goryca et al., 2019) which are expected to possess unique optoelectronic properties due to their valley-specific optical selection rules. Pulsed magnetic fields of up to 60 T are necessary to determine the excitonic properties due to the heavy carrier masses and large exciton binding energies in monolayer TMD semiconductors.

CR is specifically used to describe the transitions between adjacent LLs for free electrons or holes; therefore, it is not appropriate to describe transitions between bound states of magneto-excitons as CR. However, there are cases where the distinction is not precisely clear. When an electron-hole pair have an energy higher than the binding energy, the electron and hole can be ionized, meaning they are no longer bound to one another although they may still be correlated. Disassociation of excitons can occur by thermal excitation, optical excitation of a large number of carriers, or by applying a gate voltage to electrostatically dope the semiconductor. With strong optical excitation in a semiconductor, the large number of electrons and holes results in an excitonic Mott transition from an insulating excitonic gas to an electron-hole plasma with increasing electron-hole density; excitons are only stable in the dilute limit where the Bohr radius is much smaller than the interexciton distance. Furthermore, with a transient optical excitation pulse, there can be a dynamically changing scenario where photoexcited electrons and holes first exist in an unbound state but later combine to form excitons.

THz-TDS has been used to measure the magneto-terahertz response of electron-hole pairs while varying the temperature, excitation strength (electron-hole density), and time delay between an optical pump pulse and the THz pulse (Zhang et al., 2016). Fig. 15 shows the magnetic field dependence of the real part of the photoinduced conductivity in undoped GaAs quantum wells. 15 ps after nonresonant photoexcitation, electron-CR and heavy hole-CR features are clearly identified, with linearly dependent energies as a function of applied magnetic field. At 1 ns after photo-excitation, intraexciton transitions are revealed, exhibiting a quadratic magnetic field dependence. Density dependent measurements revealed that magneto-excitons are more stable against a Mott transition at higher electron-hole densities when experiencing a high applied magnetic field.

Recently, optical absorption measurements at high magnetic fields have been performed in both a p-doped (Li et al., 2020) and a n-doped (Li et al., 2022) monolayer of WSe₂. Because of the valley-specific optical selection rules in monolayer TMD

Fig. 15 Real part of the conductivity in the THz range for optically excited electron-hole pairs in undoped GaAs quantum wells. (A) At 15 ps after excitation, electron- and heavy hole-cyclotron resonance dominates the spectra. (B) At 1 ns after excitation, intraexciton transitions are observed. Fig. 16 Circularly polarized absorption spectra of hole-doped monolayer TMD WSe₂ provide a method to unambiguously determine the filled Landau levels in both the K and K' valleys. By tuning the carrier density, the 2DHG can become unstable against changes in LL filling and spontaneously valley polarize, as seen in (D) around 40 T. Permission from Li J, Goryca M, Wilson NP, Stier AV, Xu X, Crooker SA (2020) Spontaneous valley polarization of interacting carriers in a monolayer semiconductor. *Physical Review Letters* 125: 147602.

semiconductors, one can selectively probe the K(K') valley with σ^+ (σ^-) circularly polarized light. At zero magnetic field, the K and K' valleys are degenerate in energy; however this degeneracy can be lifted by an external magnetic field which breaks time-reversal symmetry. With the use of a single circular polarizer one can probe optical transitions in both the K and K' valley simply by changing the direction of the applied magnetic field. Fig. 16 shows optical absorption spectra up to 60 T in a doped monolayer of WSe₂. Excitons are excited into the Fermi sea of free carriers and the resultant spectra display remarkable features depending on the doping level and magnetic field. In some cases, the 2D hole gas (2DHG) is unstable against changes in LL filling and becomes valley polarized. These studies highlight the importance of electron-electron interactions in monolayer TMDs.

Conclusion

CR in semiconductors has been discussed with an emphasis on the various experimental techniques that can be employed and the information that can be extracted. CR has been applied to a wide variety of different bulk materials and heterostructures, including elemental semiconductors, wide and narrow gap III-Vs, II-VIs, and dilute magnetic systems.

Though only a limited number of examples have been given here, the same principles apply to all materials. Whenever better material becomes available, CR reveals more about the band structure; as experimental facilities push toward higher fields, the technique can be extended to more imperfect crystals and structures.

This article has concentrated on FIR absorption as a measurement technique for CR. Transitions from higher to lower LLs have been shown to produce emission at the CR energy in a variety of studies over the past 40 years. Indeed, CR laser action has been demonstrated (Unterrainer et al., 1990). While such emission has often been touted for spectroscopic applications, it is beyond the scope of the present article.

Acknowledgments

Work at the National High Magnetic Field Laboratory on semiconductors is supported by National Science Foundation Cooperative Agreement No. DMR- 1644779, the Department of Energy (DOE) and the DOE BES program "Science at 100 T". Development of high-frequency techniques has been greatly aided by grant LDRD-ER 20200285. Oxford University is thanked by JS for the provision of a visiting professorship that greatly facilitated some of the work described in this Chapter.

Abstract

An interaction event between an electron and a target material is called inelastic if the electron loses some or all of its energy. The general theory of the inelastic scattering cross-section is first developed before being specialized to interband transitions, plasmon excitations, vibrations at surfaces, core-electron excitations, and (e^- , $2e^-$) scattering. Examples are provided to illustrate how the elementary excitations of each method provide information about the atomic structure and electronic properties of materials, often in conjunction with density-functional calculations.

- Differential cross-section for inelastically scattered electrons, including dielectric formulation for interband transitions.
- Extensions to plasma excitations, vibrations at surfaces, excitations of core electrons, and (e^- , $2e^-$) scattering.
- Example of each application of inelastic electron scattering.
- Discussion of theoretical and computational approaches to inelastic scattering, including symmetry analysis, identification of paths in multiple scattering, and density functional methods.

Introduction

Inelastic electron scattering phenomena are used to obtain information on the electronic properties and atomic structure of materials. An interaction event between an electron and a target material is called inelastic if the electron loses some or all of its energy. Otherwise, the event is called elastic. Any energy loss by the electron is equal to the energy gained by the material and is characteristic of the type of scattering event. The measurement of an inelastic event determines the energy transferred and the rate of this transfer, which provides physical information about the elementary excitations of the material.

Inelastic interactions can be grouped according to different energy transfer regimes that form the basis of the principal experimental techniques. Historically, inelastic electron scattering was developed prior to the availability of continuous energy sources from dedicated storage rings. In fact, under certain circumstances, electronic excitations are equivalent to photon excitations in that they can be described within a common conceptual and theoretical framework.

An electron is an elementary particle with a mass m and, owing to its wave nature, has a de Broglie wave number $k = p/\hbar$, where $p = mv$ is the momentum of the electron, v is its velocity, and $\hbar$ is Planck's constant divided by 2π . The kinetic energy is expressed classically by $E = \frac{1}{2}mv^2$, where $v = |v|$. Electrons have a negative charge e and a nonclassical angular momentum (spin). These properties play a central role in the interactions between electrons and their environment and constitute the basis of a wide range of spectroscopic techniques.

Owing to their unique properties, there are both advantages and disadvantages to using electrons as a probe in analytical applications. Spin-polarized or spin-averaged beam of electrons are readily created, electrons can be accelerated to any energy, and focused on a target at will. After they interact with the target material, electrons can be analyzed according to their intensity, momentum, energy, and spin polarization. In the final state, there are, even in an idealized single-scattering event, two electrons that arbitrarily share the initial energy. These electrons are indistinguishable, which makes the interpretation of the results especially challenging.

Cross-section for inelastic scattering

Electron-atom scattering is the cradle of today's understanding of the quantum mechanics of many solid-state interactions. Electron–solid interactions, however, not only present a wealth of phenomena to aid the development of modern physics, but have also made spectroscopies based on electronic excitations one of the major sources of information on atomic and electronic structure and on the elemental composition of materials. To account for all electronic interactions, a first-principles theory should be developed, though a semiclassical approach often suffices.

The strength of the electronic interaction depends on the electronic energy and the materials, which endows the energy dependence of a type of event with dynamical information about the interaction. If the interaction is weak, the energy $\hbar\omega$ lost by the electron and the associated momentum transfer $\mathbf{q}$, involve the creation of a single excitation with an energy $\hbar\omega$ and momentum $\mathbf{q}$. In this case, the Born approximation (Merzbacher, 1961) is valid, so the initial (i) and final (f) states of the electron are given by plane waves:

$$\psi_i = e^{i\mathbf{k}_i \cdot \mathbf{r}} \quad \psi_f = f(\mathbf{k}_i) e^{i\mathbf{k}_f \cdot \mathbf{r}}, \quad (1)$$

where $f(\mathbf{k}_i)$ is the scattering amplitude. The interaction between the electron and the environment is described by a Hamiltonian containing the energy of the unperturbed sample, the energy of the electron, and the Coulomb potential $V(\mathbf{r})$ between the sample and the electron. During the interaction, energy and momentum are conserved,

$$E_i - E_f = \hbar\omega, \quad \mathbf{k}_f - \mathbf{k}_i = \mathbf{q}. \quad (2)$$

Using Fermi's golden rule (Merzbacher, 1961), the differential scattering cross-section can be expressed as

$$d\sigma = \frac{2\pi}{\hbar} |\langle \phi_f \psi_f | V | \psi_i \phi_i \rangle|^2 \delta(E_i - E_f) d\mathbf{k}, \quad (3)$$

where ϕ_i and ϕ_f are the wave functions of the target before and after the scattering, respectively.

When an electron scatters from an atom, the interaction only with the other electrons can be inelastic because no energy is transferred to the nucleus by Coulomb scattering. The most general type of energy transfer in electronic excitations produces a transition from an occupied to an unoccupied state separated by an energy equal to the energy loss of the primary electron. The differential cross-section of such a transition is obtained by integrating Eq. (3) to obtain

$$\frac{d^2\sigma}{dE dq} = \frac{8\pi}{q^3 k_i^2} \left(\frac{e^2 m^2}{\hbar^2} \right)^2 |\langle \phi_f | e^{-i\mathbf{q} \cdot \mathbf{r}} | \phi_i \rangle|^2. \quad (4)$$

The cross-section $N(E) \propto d\sigma/dE$ is dominated by processes for which the momentum transfer is small. If $\mathbf{q} \cdot \mathbf{r} \ll 1$, then $e^{-i\mathbf{q} \cdot \mathbf{r}} \approx 1 - i\mathbf{q} \cdot \mathbf{r}$, and the dipole approximation used in optics becomes applicable to inelastic electron scattering:

$$\frac{d^2\sigma}{dE dq} = \frac{8\pi}{q} \left(\frac{e^2}{\hbar^2 v_i} \right)^2 |\phi_f | \mathbf{n} \cdot \mathbf{r} | \phi_i \rangle|^2, \quad (5)$$

where $v_i = \hbar k_i / m$, $\mathbf{q} = q\mathbf{n}$, and $\mathbf{n}$ is the unit normal vector along $\mathbf{q}$.

Interband transitions

The validity of the dipole approximation means that the scattering cross-section can be related to the dielectric properties of the target material. The dielectric response,

$$\varepsilon(\mathbf{q}, \omega) = \varepsilon_1(\mathbf{q}, \omega) + i\varepsilon_2(\mathbf{q}, \omega), \quad (6)$$

depends on the energy transfer $\hbar\omega$ and the momentum transfer $\mathbf{q}$ defined in (2). Electrons interacting with the target produce a longitudinal perturbation over the long-range dipole fields. These fields attenuate the electron intensity through the absorptive part ε_2 of the dielectric constant. Since the field is screened by $1/\varepsilon$, the electron-loss function can be written as the sum of surface and bulk contributions (Raether, 1965; Froitzheim, 1977):

$$\begin{aligned} N(E) &\propto -\text{Im} \left[\frac{S}{1 + \varepsilon(\mathbf{q}, \omega)} + \frac{B}{\varepsilon(\mathbf{q}, \omega)} \right] \\ &\equiv -\text{Im} \left[\frac{1}{\tilde{\varepsilon}(\mathbf{q}, \omega)} \right], \end{aligned} \quad (7)$$

where S and B are weighting factors for the surface and bulk, respectively. The cross-section $N(E)$, therefore, contains fundamental information on the dielectric behavior of the bulk and the surface of the sample. A direct link between electron energy losses and the effective dielectric function defined in (7) is provided by the Kramers–Kronig relation (Jackson, 1975; Schattschneider and Jouffey, 1995),

$$\operatorname{Re}\left[\frac{1}{\tilde{\varepsilon}(\mathbf{q}, \omega)}\right] = 1 + \frac{2}{\pi} \int_0^\infty \frac{\operatorname{Im}[1/\tilde{\varepsilon}(\mathbf{q}, \omega')]}{\omega'^2 - \omega^2} \omega' d\omega', \quad (8)$$

which gives

$$\tilde{\varepsilon}(\mathbf{q}, \omega) = \frac{\operatorname{Re}[1/\tilde{\varepsilon}(\mathbf{q}, \omega)] - i\operatorname{Im}[1/\tilde{\varepsilon}(\mathbf{q}, \omega)]}{[1/\tilde{\varepsilon}(\mathbf{q}, \omega)]^2}. \quad (9)$$

The practical advantage of energy-loss measurements over optics lies in the fact that they cover a larger energy range than experiments with photons, which facilitates a more complete evaluation of (8). The electron energy-loss function, in fact, depends on the joint density of states (DOS), defined as the convolution of the occupied initial states and the unoccupied final states that are separated by the energy loss and are coupled by the matrix element. The optical function contains the transverse properties of the solid, which may be different from the longitudinal properties accessible to electron energy-loss spectroscopy. The differences between the transverse and the longitudinal responses are negligible for small momentum transfer $\mathbf{q}$ (the random phase approximation). For higher values of $\mathbf{q}$, multipole transitions are well resolved in electron-induced transitions, but are strictly forbidden in optics.

Inelastic interactions are responsible for the intensity attenuation of electrons within a bulk material. The characteristic quantity for the penetration depth of the electrons is called the mean free path Λ the value of which depends on the available excitations at a particular energy. For the range of energies ~ 30 – 100 eV, Λ has values comparable to interatomic distances (Schnatterly, 1979). Thus, the experiments contain information mainly on the surface properties (the S-term in Eq. 7). In optics, on the other hand, photons penetrate deeply into the target material, so the information is dominated by the bulk DOS (the B-term in Eq. 7). Transitions that are characteristic of the surface (e.g., surface states, adsorbates) help to distinguish between bulk and surface excitations.

Plasmon excitations

The cross-section in (7) attains peak values for $\varepsilon_1 = 0$ and $\varepsilon_2 = 0$. This condition corresponds to no charge-density fluctuations caused by the incident electrons. A longitudinal plasma wave along the crystal produces long-range Coulomb forces between positive and negative charges and excites collective excitations. These are called plasmons in the case of a quasi-free electron gas. The plasmon energy is obtained from the Fourier modes of the electron density,

$$\rho(\mathbf{r}) = \sum_{\mathbf{k}} \rho_{\mathbf{k}} e^{-i\mathbf{k} \cdot \mathbf{r}}. \quad (10)$$

The $\rho_{\mathbf{k}}$ are amplitudes for harmonic density fluctuations obeying,

$$\frac{d^2 \rho_{\mathbf{k}}}{dt^2} + \omega_p^2 \rho_{\mathbf{k}} = 0, \quad (11)$$

in which ω_p is the Langmuir frequency,

$$\omega_p = \left(\frac{n_e e^2}{\varepsilon_0 m} \right)^{\frac{1}{2}}, \quad (12)$$

n_e is the bulk charge density, ε_0 is the permittivity of free space, and the energy loss due to plasmon creation is $\hbar\omega_p$. Plasmons are quantized excitations, so the energy loss is $n\hbar\omega_p$, where n is a positive integer.

Plasmon energies can be used to extract changes in the electron density that accompany changes of the electronic properties or the volume of a solid. For example, the alloy Al-3 at.% Ag shows a transition from a high-temperature phase, where Al and Ag form a homogeneous solid solution, to a regime $\sim 400^\circ\text{C}$ where Ag atoms precipitate as Ag_2Al clusters. The formation of these precipitates can be monitored by observing the plasmon energies of Al across the transition. With Ag atoms homogeneously distributed in the bulk, more volume is available at Al atoms, resulting in a lower effective electron density, thus shifting the plasmon to lower values.

The spectra in Fig. 1 show that, at 480°C , the plasmon energy is reduced from 15.8 to 15.5 eV signaling a 3.8% volume reduction. At temperatures below 440°C , Ag_2Al precipitates form that are largely decoupled from the aluminum matrix, thus leaving the volume and electron density unaltered from their values in pure Al. Thus, there is no change in the plasmon energy.

Fig. 2 shows high-resolution electron energy-loss spectroscopy (HREELS) measurements of the π and $\sigma + \pi$ plasmons for the indicated monolayers of epitaxial graphene prepared on a Si-terminated 6H-SiC(0001) crystalline wafer by solid state graphitization. The spectra were recorded under identical conditions with the momentum transfer parallel to the surface ($q = 0.1\text{\AA}^{-1}$).

The frequencies of the two collective excitation modes shift to higher energies and the peaks broaden as the thickness of the epitaxial layers increases. The changes in the plasmon peaks provide information about how the electronic structure changes with increasing epitaxial thickness. In particular, the 6.3 eV loss peak of the 3–4 monolayers of epitaxial graphene is close to that of graphite. Alternatively, the intensity of the $\sigma + \pi$ mode becomes weaker with decreasing number of epitaxial layers. The loss peak at

14.5 eV of the $\sigma + \pi$ plasmon peak for single layer epitaxial graphene can be viewed as a limiting case when the out-of-plane mode vanishes, leaving only the in-plane mode.

There are detailed investigations of the dependence of plasmon excitations on the momentum transfer. For increasing values of q , the peak in the loss function moves to higher energies until the excitation decays into electron-hole pairs. In semiconductors, electron-hole pairs form a hydrogenic bound state called excitons which, for a material with an indirect band gap, such as Si, have a very long lifetime because the recombination process requires the emission of a phonon to conserve momentum.

Fig. 3 shows the dispersion of π -plasmon energies for epitaxial graphene with different thicknesses. Single layer and bilayer epitaxial graphenes show linear dispersions with q while the 3-4 monolayer structure shows a parabolic dispersion. The linear dispersion of monolayer epitaxial graphene is related to the unique band structure near the K -point of the Brillouin zone. The parabolic dispersion associated with 3-4 layers of epitaxial graphene is similar to the π plasmon dispersion of graphene.

Vibrations at surfaces

Electrons moving near the surface of a solid can excite localized and collective vibrations. The major experimental achievement in the measurement of these vibrations has been the development of near-monochromatic primary-electron beams and, additionally,

Fig. 3 Measured loss functions associated with the π plasmons of (A) single layer, (B) bilayer, and (C) 3-4 monolayer epitaxial graphene. The data are taken from $q = 0.05 \text{\AA}^{-1}$ to $q = 0.4 \text{\AA}^{-1}$. The corresponding dispersion curves are shown in (D), for (i) single layer, (ii) bilayer, and (iii) 3-4 layers of epitaxial graphene. the detection of reflected electrons with a resolution of the order of vibrational energies (a few meV). On Si(111), one of the most intensively studied surfaces, the local arrangement of atoms at and near the surface including the stretching of Si-Si bonds, has been obtained from surface phonon measurements and found to be consistent with the dimer-adatom-stacking fault model.

Adsorbates are foreign atoms that are bound to sites with a particular point-group symmetry of the surface structure. If the dipole image charge of the adsorbate has a component normal to the surface, the adsorbate can be excited into vibrational states while the modes with their dipole moment parallel to the surface are screened by a factor $1/(1+\epsilon)^2$. These selection rules are similar to those governing infrared transitions. One can determine the local symmetry by observing the number of vibrational modes. The local geometry is modeled by a rigid substrate against which the adsorbates vibrate (Ibach and Mills, 1982).

Fig. 4 shows some fundamental types of bonding arrangements. In (A), an adsorbate atom is placed at a top position, directly above a surface atom. This site would produce a single low-energy mode. In (B), the same atom is placed in a bridge position, equidistant between two substrate atoms. Energy loss would be observed at an even lower value than (A), corresponding to the normal vibrational component. If the chemical bonding were not symmetrical, then one would observe two peaks at similar energy losses. Generally, a lowering of the adsorption symmetry, such as uneven bonding, increases the number of vibrational modes (Ibach and Mills, 1982).

For molecular adsorbates (Fig. 4C and D), a high-energy loss would be due to the stretching mode of the atoms in the molecule while a low-energy loss would be due to the vibration of each atom against the substrate or the entire molecule. Hence, for molecular adsorption, one always expects at least two modes. Observation of a single mode is, therefore, evidence for the dissociative adsorption of a molecule. Apart from the number modes, the vibrational energy contains information about the chemical bond. An adsorption site on top of a substrate atom results in a higher force constant compared to an adsorbate at a bridge or hollow site, where the bond strength is shared by several atoms.

Fig. 4 Schematic description of four typical adsorption states for (A) an atop and (B) a bridge site for single atoms, and (C) a bridge site and (D) and atom site for a diatomic molecule. The springs represent chemical bonds of different strengths.

Excitation of core electrons

A special case of interband transitions is the excitation of core electrons with a binding energy E_B . The primary electron can transfer any amount of energy $E_L \leq E_i$ to the core electron. By measuring the energy loss of the primary electron, one knows the kinetic energy of the core electron after scattering, that is, how far above E_F the core electron has been excited. The excitation into states at E_F corresponds to zero kinetic energy and, hence, $E_L = E_B$. This is called the absorption edge. It is characteristic of a particular element and its chemical state and can thereby be used as a tool for chemical analysis.

Core states have almost no overlap between neighboring atoms, leading to extremely narrow bandwidths. Therefore, the energy-loss spectrum at and above the absorption edge is indicative of the unoccupied DOS at the site of the excited atom with an orbital angular momentum determined by the symmetry of the final state (Tinkham, 1964). If the final states are far above E_F , the modulations in the spectra result from single scattering, which can be used to extract local structural information near the excited atom. This is known as extended energy-loss fine structure (EELFS); the optical analog is extended X-ray absorption fine structure (EXAFS). The information obtained is a radial distribution function with peaks at the distances of nearest neighbors (Prinz and Koningsberger, 1986; Vvedensky, 1992; Rehr and Albers, 2000).

Closer to the absorption edge, the interpretation of the energy-loss near-edge fine structure (ELNES) spectrum requires a multiple scattering treatment, as in the near-edge X-ray-absorption fine structure (NEXAFS) in optics. In this regime, the type of information obtained includes bond angles between the excited atom and its nearest neighbors (Prinz and Koningsberger, 1986; Vvedensky, 1992; Rehr and Albers, 2000).

Nanotubes provide an illustration of such measurements. The chemical and physical properties can be manipulated by incorporating atoms or molecules within the tubes. Fig. 5 shows a high-resolution electron micrograph of an isolated single-wall nanotube containing C_{82} fullerenes and a schematic representation of the structure. The image reveals single Gd atoms encapsulated in the fullerene cages.

Fig. 6 displays spatially resolved ELNES spectra of the C K-edge (1s initial state) and the Gd N-edge (4d-initial state). Thus, it is possible to detect and identify single Gd atoms engaged in a complex C environment. Core-electron binding energies may show a chemical shift because the electronic charge density is redistributed in chemical bonding, thereby shifting the binding energy. The core electron binding energy of Gd shows a downward shift compared to the neutral Gd metal, which suggests a charge transfer from Gd to a C atom.

Detecting the local environment of Si in a graphene lattice has elements of local symmetry, as for lattice vibrations, and on the local bonding environment. Because of multiple scattering, and therefore, multi-atom correlations, ELNES is sensitive to both of these quantities. This goes far beyond the average local radial distribution function, a single-scattering quantity, obtained in EELFS. Si is one of the most common impurities in graphene grown by chemical vapor deposition or thermal decomposition. Thus, a better understanding of this impurity is desirable for the integration of graphene-based devices onto a silicon platform.

Fig. 7 shows the local environment of a threefold- and a fourfold-bonded Si in a graphene lattice, the corresponding ELNES measurements, and relaxed density-functional calculations. The *L*-edge ($2p$ initial state) reflects the excitation to unoccupied $3d$ states. The observed differences in the ELNES of the two coordinations are a direct indication of the occupancy of the $3d$ states due to the different coordinations. In particular, the peak at 105 eV and the shoulder at ~ 101 eV for the threefold coordinated site were reproduced by the calculations. Moreover, the absence of the peak at 105 eV but the presence of weaker peaks at ~ 102 eV and 107 eV were also confirmed by the calculations.

The relaxed structures of the threefold and fourfold coordinated Si impurities in graphene are shown in Fig. 7A. The calculations used a 200-atom graphene supercell using the Vienna *Ab-Initio* Software Package (VASP) (Hafner, 2008). For the threefold coordinated site, the silicon atom is displaced outward from the graphene surface. The fourfold Si impurity site, however, stays largely in the plane of the graphene. The threefold calculations are consistent with previous calculations while the fourfold calculations agree with conclusions drawn from experimental data.

(e^- , $2e^-$) Scattering

A general, yet simple, case of electron–atom or electron–solid interactions is considered in this section. Denoting the energy and momentum of the primary electron by superscript 1 and those of the target by superscript 2, the initial values (subscript i) are

$$\begin{array}{ll} \text{primary electron:} & E_i^{(1)}, \quad k_i^{(1)} \\ \text{target:} & E_i^{(2)}, \quad k_i^{(2)}. \end{array} \quad (13)$$

The corresponding final states (subscript f) are

Fig. 7 (A) Three-dimensional relaxed structures for the three-fold and four-fold Si defect structures in graphene. The Si atom is indicated in *blue* and the C atoms in graphene *gray*. (B) Calculated Si *L*-edge spectra for the three-fold (top) and four-fold (bottom) coordinated Si defect structures in graphene. (C) Measured ELNES for the three-fold (top) and four-fold (bottom) coordinated Si defect structures. Adapted from Zhou W, Kapetanakis MD, Prange MP, Pantelides ST, Pennycook SJ and Idrobo J-C (2012) Direct determination of chemical bonding of individual impurities in graphene. *Physical Review Letters* 109: 206803; ©American Physical Society.

$$\begin{aligned} \text{primary electron: } & E_f^{(1)}, \quad k_f^{(1)} \\ \text{target: } & E_f^{(2)}, \quad k_f^{(2)}. \end{aligned} \quad (14)$$

In the limit of large energy and momentum transfer, $E_f^{(1)}$ and $E_f^{(2)}$ are well above the band structure regime, so the unoccupied DOS is parabolic and does not impose additional structure upon the measurement. This interaction regime is the basis of (e^- , $2e^-$) spectroscopy for solids (McCarthy and Weigold, 1991; Artamonov et al., 1997). For atomic or molecular targets (e^- , $2e^-$), spectroscopy provides information about the wave function density in momentum space by measuring the momentum distribution of the bound electron as a function of the momentum transfer. For crystalline targets, both the momentum density and the energy dispersion of valence electrons can be determined. Since the momentum of any ejected electron can be measured, the results are not confined to the first Brillouin zone.

In a binary collision between a high-energy electron and a band electron, the conservation of energy and of momentum requires that

$$\begin{aligned} E_i^{(1)} &= E_f^{(1)} + E_f^{(2)} + E_i^{(2)}, \\ k_i^{(1)} &= k_f^{(1)} + k_f^{(2)} + k_i^{(2)}. \end{aligned} \quad (15)$$

There is, however, a continuous spectrum of single- and multiple-scattering events leads to $E_f^{(1)} + E_f^{(2)}$. To single out the event for which both conservation equations hold, the particles must be recorded in coincidence.

Fig. 8A shows the geometry of primary electrons impinging on a solid sample. A binary collision event is depicted in which a target electron acquires energy and is ejected from the back of the sample together with the primary electron. For simplicity, the scattering event is shown with coplanar initial and final wave vectors. In general, the 2π azimuthal distribution relative to the primary-electron incidence is measured to access the details of the initial state (Fig. 8B). Energy conservation requires the binary

collision event to take place as close to the surface as possible, so inelastic interactions after the principal collision are not considered. Consequently, the spectroscopic results are characteristic of the near surface region of the target material.

Fig. 9 shows an energy-band dispersion in graphite along the indicated directions in the Brillouin zone. Graphite has four populated bands, three of σ -type and one of π -type. No intensity is expected in the Γ - M and Γ - K directions from the π -band because the band is derived from C $2p$ orbitals will have a node at $q_z = 0$. Along the Γ - M direction, the lowest σ band, σ_1 disperses upward and crosses the first Brillouin zone boundary at $q = 0.8$ a.u. In the second Brillouin zone, the second σ band, σ_2 , is populated and the small splitting between σ_1 and σ_2 is not resolved. The σ_2 band continues to a maximum at $q = 1.6$ a.u., where the occupation of this band decreases and no intensity is observed above this maximum.

Along the Γ - K direction, the σ_1 band reaches the Brillouin zone boundary at a somewhat larger momentum ($q = 0.9$ a.u.), where the population changes from the σ_1 band to the third σ_3 band. Continuing to the third Brillouin zone, the σ_3 band reaches a maximum at M for momentum $q \approx 1.3$ a.u. The momentum density decreases beyond this point and the band turns over in the experimental density plot. Finally, with a nonzero offset $q_z = 0.41$ a.u., we expect the π band to be occupied. Two parabolas are observed, one for the π band and one for the σ band. The offset excludes zero momentum, so the measured bottom of the σ band has moved up in energy accordingly.

All of the foregoing features are reproduced by density functional calculations, using a linear muffin-tin orbital (LMTO) model, convoluted with a 2 eV energy broadening and 1 eV momentum broadening, which are shown in Fig. 8.

Conclusion

Electron energy-loss spectroscopy is based on the measurement of electrons that have lost energy to a target specimen due to inelastic collisions. Several examples of such measurements have been provided: interband transitions, plasmon excitations, vibrations at surfaces, core-level spectroscopy, and $(e^-, 2e^-)$ scattering. When combined with transmission electron microscopy (TEM), electron energy-loss spectroscopy is capable of a spatial resolution down to the atomic level (Spence, 2006; Egerton, 2009, 2011; Krivanek et al., 2014). This is seen in Figs. 5–7. Another advance is the combined use of scanning tunnelling microscopy and TEM (Suenaga and Koshino, 2010) to differentiate between different bonding environments near, for example, a graphene edge.

Theoretical and computational studies supplement electron energy-loss experiments. These take the form of selection rules for atomic, molecular, and solid-state systems (Tinkham, 1964), a multiple scattering analysis of the dominant paths (Vvedensky and Pendry, 1985), or a full density functional calculation (Hafner, 2008). Fig. 7 provides an example of the latter type of calculation. By comparing fully relaxed structures with ELNES measurements, the symmetry of the site should be determined along with any relaxation out of the graphene plane. Thus, density functional calculations expand the spatial range of ELNES measurements to below atomic length scales.

Abstract

Raman spectroscopy provides information on the structure, electronic and vibrational properties of crystals by the inelastic photon scattering effect. It has been a fast and nondestructive characterization tool with high spatial and spectral resolutions, which is preferential to nanostructures. The classical and quantum theory of Raman scattering effect is introduced, with the emphasis on the basic features of a Raman spectrum. Phonons in nanostructures are first exemplified by the case of a semiconductor superlattice and then extended into other systems based on their Raman spectra. The applications of resonance Raman scattering are demonstrated by studying the phonon dispersion, electronic structure and enhancement of interlayer shear phonon in carbon materials.

Introduction

Light interacts with matter in many different ways (Fox, 2010). The photons which make up the light may be absorbed or scattered or directly pass through without any interactions with the medium. Scattering specifies the phenomenon in which the light changes direction and is said to be inelastic (elastic) if the frequency of the scattered light is changed (unchanged). The phenomenon of inelastic light scattering was first postulated by Smekal (1923) and first observed experimentally in 1928 by Raman and Krishnan in molecules (Raman and Krishnan, 1928) referred to as Raman scattering since then. Over nearly one century, Raman scattering effect has been widely used to provide information on chemical structures and physical properties of materials (Jorio et al., 2011; Tan, 2019; Toporski et al., 2018), through its spectroscopy measurements (so-called Raman spectroscopy). To obtain a Raman spectrum requires a specialized apparatus with the capability to resolve a relatively weak Raman signal that is much close in energy to the elastically scattered light. Thanks to the developments of advanced apparatus (Demtroder, 2003) like lasers, charge-coupled detectors, optical filters, etc., modern Raman spectroscopy (Smith and Dent, 2019) becomes an essential tool to study the electronic (Schuller, 2006) and vibrational (Stroscio and Dutta, 2001) properties of nanostructures.

Nanostructure features a typical size in the range 1~100 nm in either one (called two-dimensional system, 2D system), two (one-dimensional system, 1D system), three dimensions (zero-dimensional system, 0D system), as exemplified by a quantum well, quantum wire and quantum dot (Davies, 1997), respectively. Notably, nanoplate (quasi-2D system), nanowire (quasi-1D system) and nanocrystal (quasi-0D system) are regularly used as the typical size is larger than (but close to) the characteristic length understudied. The reduced size of nanostructure distinguishes its Raman scattering effect from the bulk case (Zhang, 2012), from the aspects of the energy dispersion, momentum conservation and symmetry of vibration modes. As the quantized electrons are

confined in a square/parabolic quantum well, there are similar quantized phonons that are confined within a phonon quantum well, as illustrated in Fig. 2(b). In addition, as the surface-to-volume is significantly increased in nanostructures, various types of surface/interface-associated phonons appear. The constraints by momentum conservation in Raman scattering process are degraded as the momentum uncertainty ($\Delta q \leq \hbar/\Delta r$) inevitably increases due to the reduced size in nanostructures. It will include those phonons with momentum lying within Δq to participate in the Raman scattering events. The symmetry of vibration mode, which determines if the mode is Raman active or not, is reduced as the dimensionality of nanostructures decreases. It may allow the observation of those forbidden modes in bulk cases. On the other hand, the quantized electrons feature a large density of states, which is readily exploited to enhance those weak Raman signals in both nanostructures and bulk structures. It is enabled by the resonance electronic transition (Cardona, 1975; Jorio et al., 2011), so-called resonance Raman scattering (RRS), which greatly enhances the electronic transition and electron-phonon scattering rates.

Overview

The section “Raman Spectroscopy basics” provides the fundamental theory for Raman scattering effect in both classical and quantum ways from which the general features of a specific Raman spectrum are summarized. The various types of vibration modes are introduced in the section “Phonons in nanostructures” which covers the confined, interface, surface and folded vibration modes, first introduced by an exemplified superlattice (SL) and then expanded into other typical nanostructures. The third section is given to “Resonance Raman scattering in nanostructures” which specifies the contributions of resonance electronic transition to the Raman intensity enhancements and the applications to study the phonon dispersion, electronic structure and enhancement of interlayer shear phonon in carbon-related materials.

Raman spectroscopy basics

Raman scattering effect can be understood simply by the classical electromagnetic theory (Cardona, 1975; Jorio et al., 2011). An incident electric field E when applied to a solid will induce a polarization P resulting $P = \epsilon_0 \chi E$, with ϵ_0 and χ the permittivity and the electronic susceptibility of the medium, respectively. χ is to measure the ability of the incident electric field to shake the electrons of atoms in the solid, as illustrated in Fig. 1(a), which is naturally modulated by the lattice vibration with a frequency ω_q in the solid,

Fig. 1 (a) Schematics show how the lattice vibration changes the electronic susceptibility χ of the diatomic linear chain. When the two atoms get closer and far away along the chain direction, it will be respectively harder and easier for the electric field to shape the electron clouds. (b) Schematics show the third-order process to describe the Raman scattering process in crystals. The horizontal line is the electronic energy level and the solid (dashed) line is the real (virtual) state. The large upwards $i \rightarrow m$ and downwards m (including m_1 and m_2) $\rightarrow i$ arrows represent photon absorption and emission by electrons, while the small downwards ($m \rightarrow m_1$) and upwards ($m \rightarrow m_2$) arrows represent respectively the electron losing (obtaining) energy to (from) the lattice by an electron-phonon scattering event, accordingly known as Raman Stokes (anti-Stokes) process. Rayleigh scattering refers to the case without any energy changes of the electron in m state. (c) One artificial Raman spectrum to show the spectral features and the typical parameters. Rayleigh (at 0 cm^{-1}) intensity is always much stronger and it has to be filtered out for any Raman measurements. The Stokes processes ($>0 \text{ cm}^{-1}$) are normally stronger than the anti-Stokes processes ($<0 \text{ cm}^{-1}$) due to phonon creation/annihilation statistics. Raman peaks have a Lorentz lineshape featured by Peak, Intensity and the full width at half maximum (FWHM). In specific cases, the Raman features exhibit a Breit-Wigner-Fano (BWF) lineshape. Notably, the real Raman spectrum contains a baseline determined by the noise performance of the measurement system.

to the first-order, $\chi = \chi_0 + \left(\frac{\partial\chi}{\partial Q}\right)_0 Q(\omega_q)$, with $Q(\omega_q) = Q \sin \omega_q t$ the atomic displacements. In light scattering experiments, E is oscillating at an optical frequency ω_i , $E = E_0 \sin \omega_i t$. The polarization induced by electric field now becomes

$$P = \varepsilon_0 \chi_0 E_0 \sin \omega_i t + \frac{A}{2} [\cos(\omega_i - \omega_q)t - \cos(\omega_i + \omega_q)t] \quad (1)$$

with $A = \varepsilon_0 \left(\frac{\partial\chi}{\partial Q}\right)_0 Q E_0$. Eq. (1) points out that light will be scattered both elastically at a frequency ω_i (Rayleigh scattering) and inelastically, being downshifted (emission of a phonon) by the vibration frequency ω_q in the solid (Raman Stokes process) or upshifted (absorption of a phonon) by the same frequency ω_q (Raman anti-Stokes process). The differential Raman scattering cross section is obtained by (Cardona, 1975)

$$\frac{d\sigma}{d\Omega} = \frac{\omega_s^4}{(4\pi)^2 c^4} \left| \hat{e}_L \cdot \left(\frac{\partial\chi}{\partial Q}\right)_0 Q(\omega_q) \cdot \hat{e}_S \right|^2 \quad (2)$$

where the optical frequency of scattered light $\omega_s = \omega_i \pm \omega_q$ as indicated in Eq. (1), c the speed of light in the medium, $\hat{e}_L$ ($\hat{e}_S$) the unit vector representing the polarization of the incident (scattered) light. The Raman tensor can be further defined from Eq. (2), as $R = \left(\frac{\partial\chi}{\partial Q}\right)_0 \hat{Q}(\omega_q)$, with $\hat{Q} = Q/|Q|$ the unit vector, which is a third-order tensor. The full list of Raman tensors to seven types of crystal systems can be found in textbooks (Jorio et al., 2011; Zhang, 2012). Raman tensor is key to probe the symmetry of lattice vibration, implemented in polarized Raman spectroscopy measurements.

A quantum mechanical description of Raman scattering effect is based on the so-called Fermi's Golden Rule, which is used to calculate the transition probability per unit time when considering the optical properties of solids (Fox, 2010; Jorio et al., 2011). W_{if} describes a transition from an initial state $|i\rangle$ to a final one $|f\rangle$, which results

$$W_{if} \cong \frac{2\pi}{\hbar} |\langle f|H'|i\rangle|^2 \rho(E_f) \delta(E_f - E_i) \quad (3)$$

with H' the Hamiltonian to account for the interaction between the electromagnetic radiation and the crystal, $\rho(E_f)$ density of final states assuming the discrete initial state. In the first-order Raman scattering process, as shown in Fig. 1(b), H' includes three types of interactions, which can be interpreted as three steps: (1) the incident light excites the electron from an initial state $|i\rangle$ with energy E_i , to a higher energy state $|m\rangle$ with energy E_m from a laser (E_L). The solid line of state $|m\rangle$ represents a real electronic state, allowing a resonant light absorption process. (2) The electron is further scattered by a phonon to a "virtual" state (dashed line) $|m_1\rangle$ (Stokes) or $|m_2\rangle$ (anti-Stokes). Noted virtual states are usually displayed by dashed lines and, within perturbation theory, they are described by a linear combination of the electron eigenstates of the system with a large energy uncertainty and a small lifetime to compensate for the uncertainty principle. (3) The scattered electron finally decays back to the state $|i\rangle$ by emitting the scattered light. Noted the whole system is now labeled as the state $|f\rangle$ since additional phonon is emitted or absorbed with respect to the initial state $|i\rangle$. The differential Raman scattering cross section is accordingly obtained by third-order perturbation theory (Jorio et al., 2011) which gives

$$\frac{d\sigma}{d\Omega} \propto |\langle f|H'|i\rangle|^2 = \left| \sum_{m,m'} \frac{M^{op}(k_i - q, im') M^{ep}(q, m'm) M^{op}(k_i, mi)}{(E_L - \Delta E_{mi})(E_L - \hbar\omega_q - \Delta E_{m'i})} \right|^2 \quad (4)$$

in which $\Delta E_{m'i} = (E_{m'} - E_i) - i\gamma$, where m and m' denote the two excited intermediate states, γ denotes the broadening factor of the resonance event, M^{op} and M^{ep} respectively denote the electric dipole matrix elements of the electron-photon and the electron-phonon interactions. A high-order Raman process, having the various transition diagrams (Yu and Cardona, 2010), can be described by high-order perturbation theory. The denominator in Eq. (4) determines the resonance condition in RRS, which is classified as an incident resonance when $E_L = E_m - E_i$, or a scattered resonance when $E_L - \hbar\omega_q = E_{m'} - E_i$. The resonance effect is essential to the observations of measurable Raman signals from nano-scale systems. A plot of Eq. (4) as a function of E_L gives the Raman excitation profile which is essential to provide the information about the electronic structure of nanostructures (Cardona, 1975).

A Raman spectrum is a plot of the intensity of the scattered light as a function of Raman shift, $\omega = \omega_i - \omega_s$, which is $\pm \omega_q$ according to Eq. (1). Thus, the spectrum exhibits a pair of peaks on the sides of the Rayleigh line, as shown in Fig. 1(c), but either one (usually the Stokes one) or both are recorded depending on the Raman filters available in the practice Raman spectrum measurements. The phonon excitation can be considered as a harmonic oscillator damped by the interaction with other excitations in the medium. Therefore, the Raman spectrum usually features a forced damped harmonic oscillator with a Lorentzian curve given by

$$I(\omega) = \frac{I_0}{\pi \Gamma_q} \frac{1}{(\omega - \omega_q)^2 + \Gamma_q^2} \quad (5)$$

in the limit where the frequency $\omega_q \gg \Gamma_q$, with Γ_q the inverse of the lifetime for a phonon, usually expressed by the full width at half maximum intensity (FWHM), $\text{FWHM} = 2\Gamma_q$. In specific cases, such as lattice vibration couples to an electronic continuum, the Raman lineshape can deviate from the simple Lorentzian curve and exhibit a so-called Breit-Wigner-Fano (BWF) lineshape, which is given by

$$I(\omega) = I_0 \frac{[1 + (\omega - \omega_0)/q\Gamma]^2}{1 + [(\omega - \omega_0)/\Gamma]^2} \quad (6)$$

where $1/q$ is a measure of the interaction of a discrete level (phonon) with a continuum of states (the electrons). ω_0 is the BWF peak frequency at maximum intensity I_0 , and Γ is the half width of the BWF peak. A pair of BWF peaks with $1/q > 0$ is plotted in Fig. 1(c). Such effect is observed in the ultralow-frequency Raman spectra of a multilayer graphene (Tan et al., 2012), as shown in Fig. 6(d). From Eq. (2), the differential Raman scattering cross section for Stokes and anti-Stokes are obtained by (Cardona, 1975)

$$\begin{aligned}\frac{d\sigma_S}{d\Omega} &\propto \langle Q(\omega_q) Q^*(\omega_q) \rangle \propto (n+1) \\ \frac{d\sigma_{aS}}{d\Omega} &\propto \langle Q^*(\omega_q) Q(\omega_q) \rangle \propto n\end{aligned}\quad (7)$$

where $n = (\exp(\hbar\omega_q/k_B T) - 1)^{-1}$ is Bose-Einstein distribution function for the phonon with energy $\hbar\omega_q$. So the intensity of Raman Stokes process is much stronger than the anti-Stokes case by noticing

$$\frac{\sigma_S}{\sigma_{aS}} \propto \exp\left(\frac{\hbar\omega_q}{k_B T}\right) \gg 1 \quad (8)$$

Finally, energy and momentum conservations can respectively be found from Eq. (3), expressed by $\delta(E_f - E_i)$, and Eq. (4), by $k_s = k_i - q$, i.e., $q \sim 0$ because k_i is much small compared to the dimensions of Brillouin zone (BZ). It is why the first-order Raman process can only probe phonons near the BZ center (Γ point). The Raman frequency of this type of vibration is not dependent on E_L , which was normally taken as the general rule for Raman spectroscopy.

In practice, an efficient collecting system is always required to pick up the relatively weak Raman signals from the strong Rayleigh line. We recommend the book "Modern Raman Spectroscopy: A Practical Approach," written by Ewen Smith and Geoffrey Dent (Smith and Dent, 2019), which can serve as an excellent introduction to the Raman measurement system and the most advanced developments. As complementary, our original work to probe the ultra-low frequency Raman spectra of multilayer graphenes can be referred to as a standard tutorial to introduce the latest advancements to detect those Raman peaks extremely closed to Rayleigh line (Tan et al., 2012).

Phonons in nanostructures

Different types of phonons in nanostructures can be exemplified by an SL, as illustrated in Fig. 2(a), which are categorized as the confined optical modes in barrier and well, the macroscopic and microscopic interface modes, and the folded acoustic mode (Tan et al., 2004; Zhang, 2012). The new 1D out-of-plane periods of SL along the growth direction shrink the BZ by folding both the optical and acoustic phonons into a smaller BZ with respect to the bulk case, as shown by Fig. 5(a). Because of the distinctive optical and acoustic vibrations, the folded optical phonons are mostly confined in the alternating layers (confined optical modes), in contrast, the folded acoustic phonons are extended into all of the constituents of an SL (Fig. 5(a)). As a typical complementary to semiconductor SLs developed in the 1980s, a twisted bilayer system from a 2D material (2DM) holds in-plane artificial periods which create an interesting folding effect on its phonon dispersion (Fig. 5(e)). The confined acoustic and optical modes appear in the case of a strongly confined nanostructure, like nanowire, nanorod and nanocrystal which are normally known as surface vibration modes (Fig. 4). Interface vibration mode is unique in an SL with the macroscopic one from the excited states of the confined optical modes and the microscopic one localized at the interface (which is also known as surface vibration mode). The macroscopic interface modes find their general dispersive behaviors on the layer thickness in multilayer 2DMs (Fig. 3(b)) and distinctive decouples between in-plane and out-of-plane phonons in a 2D van der Waals heterostructures (vdWHs) (Fig. 3(c)). In addition, interface modes apply to the sample-substrate structure (Fig. 3(d)) and the hybrid nanostructures, as exemplified by dot-in-rods in Fig. 4(d).

Confined vibration modes

Analogous to the quantization of electrons in a potential well, the frequency of lattice vibration in a "phonon potential well" is well quantized and strongly depends on the length of the potential well. Fig. 2(b) shows the calculated z component of displacements (U_z) for the highest GaAs-like LO modes, LO_1 , LO_2 , LO_3 , in a $(\text{GaAs})_{20}/(\text{AlAs})_{20}$ SL, which are strictly confined in the GaAs layer (Rückner et al., 1992). The profile formed by the displacements of either Ga or As atoms is the same as the quantized electronic wavefunction in a square potential well with the nodes increasing in a sequence of 0, 1, 2, 3, ... (Fig. 2(b)). The confined optical modes within the well layers of quantum well structures were firstly observed in GaAs/ $\text{Ga}_{1-x}\text{Al}_x\text{As}$ SLs (Jusserand et al., 1984). The frequencies of Raman peaks associated with confined phonons show blueshift as decreasing the thickness of GaAs layer, indicated by the pitch arcs labeled by 1, 2, 3, 4 which corresponds to the different confined orders, as shown in Fig. 2(b). The spatial confinement effects on the vibrations in nanostructures are further studied in GaAs/AlAs quantum wire (Comas et al., 1993), silicon nanowire (Piscanec et al., 2003), carbon nanotube (Dresselhaus et al., 2005; Jorio and Saito, 2021), Ge nanocrystal (Bottani et al., 1996), etc. Special attention is paid to the case of nanostructures with intrinsic polarization, such as SiC nanorods (Feng et al., 1988), where the long-range Coulomb interaction results in a Raman spectrum featuring a non-crystalline structure.

Carbon nanotube with a hollow core is different from the semiconductor nanowire but clearly shows the confinement effects. The carbon-related materials involve an optical phonon between the two dissimilar carbon atoms in the unit cell, featuring one single

Fig. 2 (a) Five types of vibration modes in a semiconductor superlattice (SL), including the confined optical modes in both barrier and well, the macroscopic (macro-) and microscopic (micro-) interface modes, and the folded acoustic mode. (b) Left: atomic displacements (U_z) of the topmost GaAs-like modes of a (001)-oriented $(\text{GaAs})_{20}/(\text{AlAs})_{20}$ SL for $q = (0, 0, q_z \rightarrow 0)$. The GaAs layer is centered at $z = 0$; the dashed vertical lines mark the As interface planes. Diamonds, stars, and asterisks indicate the positions of Ga, Al, and As planes, respectively. Right: Raman spectra of $\text{GaAs}/\text{Ga}_{1-x}\text{Al}_x\text{As}$ SLs in the GaAs optical frequency range. The pitch arcs labeled by 1, 2, 3, 4 correspond to the different confined orders. (c) Frequency as a function of $1/d_t$ for the two most intense G-band features (G^- and G^+) from isolated SWNTs. Insets: Left: the G-band for highly oriented pyrolytic graphite (HOPG), one semiconducting SWNT and one metallic SWNT. Right: atomic vibrations of G-band in SWNT. Lorentzian peak at 1582 cm^{-1} (G-band) for graphite (Dresselhaus et al., 2005; Jorio and Saito, 2021). In contrast, the G-band in a single-wall carbon nanotube (SWNT) consists of two main components, one vibrating along SWNT (LO phonon), locating at $\sim 1590\text{ cm}^{-1}$ (G^+), another one vibrating along the circumferential direction of the SWNT (TO phonon), lying at $\sim 1570\text{ cm}^{-1}$ (G^-), as shown by the inset in Fig. 2(c). Notably, the lineshape of G-peak is highly sensitive to whether the SWNT is metallic (BWF lineshape) or semiconducting (Lorentzian lineshape), as shown by inset in Fig. 2(c). As SWNT curvature increases, i.e., decreasing the SWNT diameter d_v , the frequency of G^- follows a monotonically descending trend both for metallic and semiconducting SWNTs as a result of the stronger spatial confinement. But it does not influence the G^+ peak since it is vibrating along SWNT without any confinements.

The extreme spatial confinements in (quasi-) 0D system, such as quantum dots and nanocrystals (NCs), make the contributions of the confined phonons to its Raman spectrum mixed with the relaxation of the fundamental momentum conservation of $q \sim 0$ required in the Raman scattering process (Sui et al., 1992; Yoshikawa et al., 1995; Zi et al., 1996). It allows those phonons near Γ point in BZ to participate in the scattering process, where the specific phonon dispersion is needed to be included to discuss the lineshape of Raman peaks. In practice, a phonon confinement model (originally proposed by Richter, Wang and Ley, known as RWL model) is widely used (Richter et al., 1981), which gives the Raman intensity in NCs with a domain size L_D as

$$I(\omega) = \int \frac{|C(0, q)|^2}{(\omega - \omega_q)^2 + (\Gamma_0/2)^2} d^3q \quad (9)$$

where $|C(0, q)| = \exp(-q^2 L_D^2 / 2\alpha)$ is the Fourier coefficient of a phonon weighting function, with α an adjustable confinement coefficient, Γ_0 is the natural broadening, ω_q is the phonon dispersion curve. The integration is over the BZ. Note, under the circumstance of a Raman peak contributed by a pair of phonon branches which are degenerated at Γ point, as shown in Fig. 2(d) for LO_2 and TO_2 , the integration must take them into account. The lineshapes of Raman peaks in NCs are exemplified by 2D NCs in monolayer WS_2 (Shi et al., 2016), as shown in Fig. 2(d). The Raman spectra of two 1L- WS_2 NCs in the energy range of the two first-order peaks E' and A_1' are plotted, as well as the good fits including the predictions from Eq. (9). The extracted L_D are 10 nm (#2-NCs) and 2.3 nm (#7-NCs). It indicates a downshift in frequency and an asymmetrical broadening toward lower frequency as L_D decreases. However, an opposite behavior is recovered for A_1' mode in 1L- WSe_2 NCs, as a result of its opposite trends of LO_2 phonon branch away from Γ point in the BZ.

Interface vibration modes

The rapidly developed 2DMs hold a set of unique interface vibrations modes, which are referred to as the interlayer shear (S) and layer-breathing (LB) modes (Zhang et al., 2013, 2015). S and LB modes correspond to the relative motions of the atomic planes which are parallel and perpendicular to the basal plane, respectively. These modes are considered as quasi-acoustic phonons because the atomic vibrations within each layer are in-phase, while the interlayer vibrations are out-of-phase. It indicates that their typical frequencies are relatively small than the optical phonons in 2DMs, as illustrated in Fig. 3(a) for the case of MoS_2 . In addition, those modes are highly dispersive as layer number increases. For an N -layer (NL) 2DM, there are $(N-1)$ pairs of S modes and $(N-1)$ pairs of LB modes, which are in sequence denoted as $S_{N,N-j}$ and $LB_{N,N-j}$ ($j = 1, 2, \dots, N-1$) with $S_{N,1}$ ($LB_{N,1}$) the one with the highest frequency. The frequencies of S and LB modes as a function of thickness are well documented by a linear chain mode (LCM) among which each layer of 2DM is simplified as a single ball with an effective mass μ . LCM gives an analytic expression as (Zhang et al., 2016)

$$\begin{aligned}\omega(S_{N,N-j}) &= \omega(S_{\text{bulk}}) \sin(j\pi/2N) \\ \omega(LB_{N,N-j}) &= \omega(LB_{\text{bulk}}) \sin(j\pi/2N)\end{aligned}\quad (10)$$

where $\omega(S_{\text{bulk}}) = \sqrt{\alpha_0^{\parallel} / \pi^2 c^2 \mu}$ and $\omega(LB_{\text{bulk}}) = \sqrt{\alpha_0^{\perp} / \pi^2 c^2 \mu}$ with c the speed of light, μ the mass per unit area in monolayers, and $\alpha_0^{\parallel}$ ($\alpha_0^{\perp}$) the force constants per unit area for the S (LB) mode. Fig. 3(b) shows the branches ($j = N-1, N-2, \dots$) for the S modes and the branches ($j = 1, 2, \dots$) for the LB modes by the scaled $\omega(S_{2,1}) = \omega(LB_{2,1}) = 1$. The normalized experimental frequencies of the S (squares) and LB modes (circles) in NL- MoS_2 by the corresponding $\omega(S_{2,1})$ and $\omega(LB_{2,1})$ perfectly match with the calculations based on LCM. The robust link between $\omega(S_{N,N-j})$ (and $\omega(LB_{N,N-j})$) and N makes itself an accurate and effective method to identify the thickness of a specific multilayer 2DM.

Interface vibration modes also apply to vdWHs which combine two different 2DMs, but have distinctive features with respect to natural 2DMs. Fig. 3(c) shows the Raman spectra of the vdWHs formed by interfacing a trilayer WS_2 (3LW) with N Layer hBN (NL-hBN, $N = 32, 44$, and 224), as compared with that of a standalone 3LW (Lin et al., 2019). The S mode in vdWHs is localized within 3LW ($S_{3,1}$) constituent, in contrast, the LB modes are well extended over the entire layers of the vdWHs, exhibiting bulk-like phonon features. It is surprising to observe more than 30 LB modes in 3LW/224L-hBN vdWHs, which are resonantly enhanced by electronic transitions related to the C exciton of the 3LW. Accordingly, the electron-phonon coupling (EPC) in 3LW/224L-hBN vdWHs happens between localized electrons confined within WS_2 constituents and bulk-like LB phonons involving all of the layers, named a cross-dimensional EPC. In addition, the specific frequency of LB phonons is well reproduced by extending LCM to include the interface force constant. The built-up cross-dimensional EPC in vdWHs allows new access to manipulate both the designable phonon excitations and the coupling to the localized electronic states by changing the constituents and interface engineering.

Surprisingly, the strong interaction between 2DM and its supported substrate behaviors is just like a spring to active the sample-substrate interface vibration modes, as shown in Fig. 3(d). The low-frequency Raman spectra of 1L- WS_2 samples as grown on both sapphire and silicon substrates clearly show an interface mode with its frequency close to $\sim 30 \text{ cm}^{-1}$ (Xiang et al., 2021). The distinguish of its origin from those low-frequency interlayer S and LB modes is by noticing the monolayer feature of WS_2 sample. It is shown that the strong sample-substrate interface stems from the unavoidable interface tensile strain introduced in the process of CVD growth, which is not supposed to exist in 2DMs obtained by mechanical exfoliation. Statistically, the frequencies of interface vibration peaks are quite similar for various as-grown WS_2 flakes, ruling out the possible sample-dependent phonon behaviors. These results introduce low-frequency Raman spectroscopy as an effective tool in probing sample-substrate interactions which are naturally subject to 2DMs.

Surface vibration modes

Surface vibration modes, as the microscopic interface mode of an SL (Fig. 2(a)), specify those modes strongly localized near the surface. In the multilayer 2DMs, the interlayer vibrations introduced above hold a branch of surface modes, as illustrated in Fig. 4(a) by the dashed line for multilayer graphenes, where the atomic displacements become much more surface-confined as the number of layers increases (Tan et al., 2012). The corresponding frequency in the bulk case must be zero as expected from the descending trend of the branch. Another example of surface mode is the radial breathing mode (RBM) of a SWNT, which corresponds to the coherent vibration of the carbon atoms in the radial direction, as if the tube were "breathing" (Saito et al., 1998), as shown in Fig. 4(b). It can be constructed by the roll-up of an out-of-plane transverse acoustic phonon (σTA) at Γ point in

the BZ of monolayer graphene. RBM features are unique to carbon nanotubes and occur with frequencies between 120 and 350 cm^{-1} for SWNTs for diameters in the range $0.7 \text{ nm} < d_t < 2 \text{ nm}$ (Dresselhaus et al., 2005), as shown in Fig. 4(b). The relation of RBM frequency (ω_{RBM}) on d_t is expressed by $\omega_{\text{RBM}} = A/d_t + B$ with A and B parameters determined experimentally. The reciprocal dependency of ω_{RBM} on d_t is a result of spatial confinements along the circumferential direction of the SWNT. RBM features find the applications to study d_t to probe the electronic structure through its intensity (I_{RBM}) and to perform an (n, m) assignment of a single isolated SWNT from analysis of both d_t and I_{RBM} , as to be introduced in the section “Resonance Raman scattering in nanostructures.”

In contrast to the long SWNT, there are both RBMs and confined extensional (EXT.) vibration modes vibrating along the long axis of the nanorod, (Miscuglio et al., 2016), as illustrated in Fig. 4(c). Different from SWNT, ω_{RBM} of a nanorod is described by

$$\omega_{\text{RBM}} = \frac{2\tau_n}{D} \sqrt{\frac{E(1-\nu)}{\rho(1+\nu)(1-2\nu)}} \quad (11)$$

with D the diameter of the nanorod, ρ the mass density, E the Young modulus, ν the Poisson ratio, and τ_n the n th root of the equation $\tau J_0(\tau) = (1-2\nu)/(1-\nu) J_1(\tau)$. $J_0(\tau)$ and $J_1(\tau)$ are Bessel functions. The frequency of the confined EXT. mode is given by

$$\omega_{\text{EXT}} = \frac{2n+1}{L} \pi \sqrt{E_{\parallel}/\rho} \quad (12)$$

where L is the nanorod length, $E_{\parallel}$ is the Young modulus along the long axis of the nanorod. The factor $(2n+1)$ with $n = 0, 1, 2, \dots$, accounts for the number of confined modes. The confined EXT. mode has a smaller frequency ($\sim 7.5 \text{ cm}^{-1}$) with respect to the RBM ($\sim 15.7 \text{ cm}^{-1}$) because of the fewer confinements in the long axis. To hybrid nanorod with a nanodot to form the dot-in-rods (like CdSe/CdS core-shell) structure is prominent for light-emitting applications (Bruchez et al., 1998). The dot-in-rods hybrid structure has interesting impacts on the confined surface vibrations (Miscuglio et al., 2016). Unlike nanorods, the fundamental acoustic vibrations of a nanodot are separated into ellipsoidal (ELL.) and spheroidal modes (RBMs), whose frequencies can be obtained by Lamb's theory and assigned by the radial (n) and angular quantum (l) numbers. Accordingly, $l = 0$ represents the spheroidal modes with their frequencies expressed by

$$\omega_{\text{RBM},n} = S_n \frac{2c_L}{D} \quad (13)$$

where c_L is longitudinal sound velocity, D is the diameter of the sphere, and the first two coefficients for $n = 1, 2$ are $S_1 = 2.87$ and $S_2 = 6.16$. The Raman spectrum of a CdSe nanodot ($D \sim 5.7 \text{ nm}$) is shown in Fig. 4(c) with each mode explicitly assigned by a (n, l) . Noted its $\omega_{\text{RBM},0} \sim 16.5 \text{ cm}^{-1}$ is much close to that in CdS nanodot ($\omega_{\text{RBM}} \sim 15.7 \text{ cm}^{-1}$). Fig. 4(c) shows the Raman spectrum of a CdSe/CdS dot-in-rods, with $D \sim 5.7 \text{ nm}$ for CdSe dot and $D \sim 5.75 \text{ nm}$ for CdS rod. The Raman peak of the confined EXT. mode is much similar to that of the nanorod. It can be attributed to the nonlocality of this vibration that extends over the full rod volume and therefore is less affected by the local modification of the core. However, the RBM peak is divided into a fundamental RBM (F-RBM) and a high-order RBM (H-RBM). As illustrated by the inset in Fig. 4(c), F-RBM shows a symmetric dilatation/contraction motion located in the central region of the rod, while H-RBM exhibits a symmetric oscillation off-center of the rod. The splitting of F-RBM and H-RBM increases with increasing core size. This can be understood in the way that dot-in-rods architecture leads to a reduction of the sound velocity in the core region of the rod. Dot-in-rods architecture can be exploited as a tool to tune exciton-phonon coupling in nanocrystal heterostructures.

Surface optical (SO) vibration modes were first predicted by Fuchs and Kliever (1965) and first observed by Ibach using inelastic electron scattering (Ibach, 1970). The dispersion relation of a SO mode in an infinitely long cylindrical wire can be written (in the limit $q \gg \omega/c$)

$$\omega_{\text{SO}}^2 = \omega_{\text{TO}}^2 + \frac{\omega_p^2}{\epsilon_{\infty} + \epsilon_m f(x)} \quad (14)$$

with $x = qr$, where ω_{TO} is the TO mode frequency at zone center, ω_p is the screened ion plasma frequency given by $\omega_{\text{LO}}^2 = \omega_{\text{TO}}^2 + \omega_p^2/\epsilon_{\infty}$, ϵ_{∞} is the high-frequency dielectric constant of bulk materials, ϵ_m is the dielectric constant of the overlaying media to wire, $d = 2r$ is the wire diameter, and $f(x)$ is obtained from the eigenvalue equation

$$f(x) = \frac{I_0(x)K_1(x)}{I_1(x)K_0(x)} \quad (15)$$

with $I_j(x)$ and $K_j(x)$ are Bessel functions. Raman spectra of GaP nanowires in air ($\epsilon_m = 1$), dichloromethane ($\epsilon_m = 2$), and aniline ($\epsilon_m = 2.65$) are plotted in Fig. 4(d) (Gupta et al., 2003). They feature two sharp peaks, which are identified with the TO ($q = 0$) and LO ($q = 0$) modes, in reasonable agreement with bulk crystalline GaP, and a third one assigned to SO by its sensitivity to the interfaced external medium. Noted, unlike the surface acoustic modes discussed above, the observation of SO mode here is enabled by an inherent length scale ($\sim 40 \text{ nm}$) in the nanowires due to either the self-oscillating nature of the filament cross section or polynuclear growth (Gupta et al., 2003).

Folded vibration modes

Folded vibrations modes in a binary SL stem from the new 1D out-of-plane translational periods of the alternating layers (Cardona and Guntherodt, 1989), i.e., $L = n_1 a_1 + n_2 a_2$, where $d_1 = n_1 a_1$ and $d_2 = n_2 a_2$ are layer thickness for AlAs and GaAs, as

Fig. 5 (a) Sketch of GaAs/AlAs SL structure and dispersion curves of a photon (oblique solid line) and longitudinal phonons of bulk GaAs and AlAs (dashed line) and SL (solid line) (b) Raman spectrum of SL GaAs/AlAs. $A_1^{(1)}$ and $B_2^{(1)}$ are assigned to the folded acoustic phonons. (c) Top: Crystallographic SL and moiré pattern in (5,7)-tBLM with $\theta = 10.99^\circ$. Dashed (red) and solid (green) parallelogram corresponds to the moiré unit cell and crystallographic SL unit cell of the tBLMs, respectively. Bottom (left): the reciprocal lattice of (5,7)-tBLMs. The large blue and orange hexagons are the first BZ of top and bottom MoS₂ layers, and the dashed (red) and solid (green) hexagons represent the Wigner-Seitz cells of the reciprocal lattices corresponding to the moiré and crystallographic SL, respectively. Bottom (right): Schematic diagram of moiré basic vectors ($\mathbf{g}_i$, $i = 1, 2, 3$) for $\theta \leq 30^\circ$. (d) Raman spectra of tBLMs in the region of 50–365 cm⁻¹. Different shapes and color symbols represent the Raman modes in different phonon branches. The Raman spectra of 1LM and 3R-BLM ($\theta = 0^\circ$) are plotted for comparison. (e) The comparison of calculated and experimental frequencies of moiré phonons dependent on $|\mathbf{g}|$. Panel (a): Reproduced from Zhang S.-L. (2012) *Raman Spectroscopy and its Application in Nanostructures*. John Wiley & Sons Ltd. Panel (b): Reproduced from Colvard et al. (1980) *Physical Review Letters* 45: 298–301. shown in Fig. 5(a) for $n_1 = 3$ and $n_2 = 2$, respectively. The original BZ in bulk case, $-\pi/a$ to π/a , now is folded into a small one in SL, $-\pi/L$ to π/L . The folded optical phonons in AlAs and GaAs are strongly confined within each layer (confined vibration modes). But the acoustic phonons which are similar to each other in AlAs and GaAs produce $(p = n_1 + n_2)$ folded phonons, as illustrated in Fig. 5(a) for $p = 8$. Interestingly, the non-intersect optical and acoustic branches in bulk GaAs and AlAs now overlap with each other, which makes the acoustic phonon Raman active in the GaAs/AlAs SL. Fig. 5(b) shows the Raman spectrum of a GaAs/AlAs SL which presents a folded acoustic doublet ($A_1^{(1)}$ and $B_2^{(1)}$) (Colvard et al., 1980).

Instead of the 1D out-of-plane translational periods along the growth direction in the semiconductor SL, as drawn in Fig. 5(a), in-plane 2D translational periods are recently discovered in the twisted bilayer (tBL-) 2DMs (Cao et al., 2018), as firstly exemplified by graphene and then rapidly extended to other 2DMs. It is achieved by rotating (with an angle θ) the two crystal networks in bilayer system with respect to each other. Fig. 5(c) shows the crystallographic and moiré SLs for tBL-MoS₂ with $(m, n) = (5, 7)$, denoted as (5,7)-tBLM (Lin et al., 2018). The corresponding $\theta = 10.99^\circ$ is obtained based on the relation $\cos\theta = (m^2 + 4mn + n^2)/2(m^2 + mn + n^2)$. The lattice constants for crystallographic (L) and moiré (L^M) SLs are receptively, $L = a_0 |m - n| / 2 \sin(\theta/2)$ and $L^M = a_0 / 2 \sin(\theta/2)$. They are equal for the case of $|m - n| = 1$. The Wigner-Seitz cells corresponding to crystallographic and moiré SLs are shown in Fig. 5(c), which clearly divide the first BZs of top and bottom monolayers into the small hexagons. The magnitude of the moiré reciprocal lattice vector ($\mathbf{g}$) is obtained by $|\mathbf{g}| = 2b \sin(\theta/2)$, with $b = 4\pi/\sqrt{3}a_0$. The trace of $\mathbf{g}$ in the first BZ of the monolayer MoS₂ (1LM) as a function of θ is demonstrated in Fig. 5(c). It indicates that the phonons of 1LM with $\mathbf{q} = \mathbf{g}$ are folded back to the Γ points in the Wigner-Seitz cells and accordingly become Raman active. The Raman spectra of tBLM with θ ranging from 0° to 49° are

shown in Fig. 5(d). Seven series of θ -dependent Raman modes are identified as folded vibration modes associated with ZA, TA, LA, E' (TO₁), E' (LO₁), E' (TO₂) and A_1' branches in 1LM, accordingly assigned as FZA (F stands for “folded”), FTA, FLA, FE' (TO₁), FE' (LO₁), FE' (TO₂) and FA_1' , respectively. Fig. 5(e) shows the experimental frequencies of moiré phonons mapped onto the theoretical dispersion curves traced by g. The good agreement indicates that the moiré phonons can serve as a fingerprint to determine θ of the tBLMs.

Similar to the confined folded optical phonons in each alternating quantum potential well, as shown in Fig. 2(a), the optical phonons of tBL-2DMs are confined within the in-plane moiré potential well. The strength of confinements becomes extremely strong as θ gets much close to zero, as exemplified by the tBL-graphene (tBLG) with $\theta = 0.987^\circ$ (it corresponds to $L^M/a_0 \sim 3328$). It makes the G-band due to the stretching of the C—C bonds highly localized at those regions referred to as AB- and BA-stacked domains, strain solitons (SP) and topological points (AA) (Gadelha et al., 2021). To probe those G-bands, including G_+ from SP region and G_- from AA region, needs a nano-Raman spectroscopy. These strongly confined moiré phonons are helpful to understand phonon-related effects at atomic and nanometric scales, such as Jahn-Teller effects (Angeli et al., 2019; Shinozuka, 2021) and electronic Cooper pairing (Lian et al., 2019; Wu et al., 2018b).

Resonance Raman scattering in nanostructures

RRS is key to detecting those Raman peaks subject to weak intensities in both bulk cases and nanostructures. But RRS in nanostructures may show distinctive or even anomalous features. As discussed in the section “Raman spectroscopy basics,” Raman shift is not dependent on the exploited incident laser wavelength, which is considered as one general rule for Raman scattering effect. Fig. 6(a) shows the Raman spectra of monolayer graphene under different excitation energies, whose 2D-band (Note 2D is not referred as “two-dimensional,” but double of D-band in frequency.) is linearly dispersive as E_L increases, with a slope of $\sim 100 \text{ cm}^{-1} \text{ eV}^{-1}$, in contrast to the G-band (Wu et al., 2018a). The microscopic intra-valley and inter-valley scattering

Fig. 6 (a) Left: One-phonon first-order and two-phonons second-order, resonance Raman spectral processes in monolayer graphene. Middle: Phonon dispersion of monolayer graphene. Right: Raman spectra of monolayer graphene measured at various excitations in the G- and 2D-bands regions. (b) The electronic 1D density of states (DOS) per unit cell for two (n,m) zigzag nanotubes: (up panel) the $(9,0)$ nanotube which has metallic behavior, (bottom panel) the $(10,0)$ nanotube which has semiconducting behavior. Also shown is the DOS for the graphene sheet. (c) Left: Raman spectra of the tangential G-band modes of SWNT bundles measured with several different laser lines, on a sample with $d_t = 1.37 \pm 0.18 \text{ nm}$. Right: Resonant transition energies E_{ii} vs d_t . The vertical solid line is the average d_t and the vertical dashed lines denote the d_t distribution width. Crosses are for semiconducting SWNTs and open circles for metallic SWNTs. (d) Raman spectra of AB-stacked 4LG and $t(1+3)$ LG in the regions of C, R-, G- and 2D-bands. C_{31} and C_{32} denote the observed shear modes in $t(1+3)$ LG, which is from the 3LG constituent, in contrast to C_{41} in AB-stacked 4LG. The dashed lines are fit to G-band, which features two subpeaks, G_- and G_+ , in $t(1+3)$ LG. Panel (a): Reproduced from Wu et al. (2018) *Chemical Society Review* 47: 1822–1873. Panel (b): Reproduced from Saito et al. (1998) *Physical Properties of Carbon Nanotubes*. Imperial College Press. Panels (a) (left and middle) and (c): Reproduced from Jorio et al. processes for G- and 2D-bands are shown in Fig. 6(a) (Jorio et al., 2011). G-band belongs to one-phonon (the degenerate TO/LO) first-order scattering process with $q \sim 0$ (Γ point). 2D-band involves a two-phonon (two TO near K point) second-order scattering process, which has a $q \sim 2k \sim K$ (BZ boundary). $E_L = (E_m - E_i)$, proportional to k , applies to all the vertically electronic transitions, which is responsible for the strong Raman intensity observed in monolayer graphene which just has one atomic layer. On the other hand, ω_q of TO phonon is linearly increased as q gets away from the K point due to Kohn anomaly (Lazzeri and Mauri, 2006) (Fig. 6(a)). Accordingly, the increasing E_L (i.e., k) will lead to an increase in ω_q through the momentum conservation law $q \sim 2k$. Notably, q involved in the Stokes and anti-Stokes for the 2D band are different from each other, creating a frequency discrepancy between its Stokes and anti-Stokes components (Cong et al., 2018; Tan et al., 1998) due to the dispersive feature of TO phonon (Thomsen and Reich, 2000). Such a frequency discrepancy had been widely detected in bulk graphite, graphite whiskers, and multi-walled carbon nanotubes.

The above discussion indicates the RRS in nanostructures is tightly associated with their electronic transitions which are mediated by the density of states (DOS). Of particular interest has been the 1D DOS in a carbon nanotube (Saito et al., 1998), as exemplified by metallic (9,0) and semiconducting (10,0) zigzag nanotubes in Fig. 6(b). The DOS has a value of zero for the semiconducting nanotubes at $E = 0$ but is non-zero (and small) for the metallic nanotubes. The comparison between the 1D DOS for nanotubes and the 2D DOS for a graphene layer is included in Fig. 6(b). Nanotube exhibits lots of sharp peaks, which leads to the DOS-enhanced electronic transition as compared with graphene. A pair of sharp peaks in symmetry with respect to $E = 0$ specifies the resonance transition energy E_{ii} . Fig. 6(c) shows the Raman spectra of G-band modes of carbon nanotube bundles measured under different laser lines (Pimenta et al., 1998). The lineshapes indicate the presence of both semiconducting and metallic carbon nanotubes in bundles. Kataura plot was proposed to interpret the RRS effects in nanotubes, where Kataura and co-workers displayed the optical transition energies for each (n, m) SWNT as a function of tube diameter d_t (Kataura et al., 1999), as shown in Fig. 6(c). As demonstrated by the links between the Raman spectra and Kataura plot, RRS in bundles resonantly probes the SWNT with different d_t . Only those SWNTs with E_{ii} closed to the laser energy E_L are present in the Raman spectra. Alternatively, as indicated by the vertical lines in Fig. 6(c), G-band of a SWNT with a fixed d_t will not show up unless $E_L = E_{ii}$. In this way, RRS finds its valuable role to study the confined electronic structure in nanostructures.

The shear mode of multilayer graphenes is usually denoted as the C mode (Tan et al., 2012; Wu et al., 2014), which features a BWF line shape in AB-stacked multilayer graphene, as exemplified by a four-layer graphene (AB-4LG) in Fig. 6(d). It is attributed to the quantum interference between the C mode and a continuum of electronic transitions near K point (Tan et al., 2012). As shown in Fig. 6(d), the intensity of C_{41} is much weaker than G-band due to its small strength of electron-phonon coupling. However, the intensities of the S modes in a twisted $(1 + 3)$ LG, labeled as $t(1 + 3)$ LG, are comparable to the G-band. They are enhanced by the RRS processes mediated by the pairs of parallel electronic bands, induced by the intralayer twisting. This intensity enhancement of the S mode masks the weak BWF profile to give an overall Lorentzian profile, even though there is no band gap opening near K point in $t(1 + 3)$ LG (Wu et al., 2014).

Conclusion

Raman spectroscopy has been used to study the science of nanostructures, recovering more and more fundamental aspects of their electronic and vibrational properties. In this encyclopedia, we firstly introduce the basics to understand the Raman scattering effect and the general features of a Raman spectrum. Followed is given to the phonon in nanostructures based on their Raman spectra, which is firstly exemplified by a semiconductor SL and then extended to other cases. Of particular interest is RRS in nanostructures, which can be exploited to significantly enhance the weak Raman peaks and to probe the confined electronic structures. The rapid developments of Raman spectroscopy applied into nanostructures are readily beneficial from the non-stop improvements in experimental techniques, such as the nano-Raman spectroscopy and the available laser lines for RRS. For the future perspectives, developing the specific Raman spectroscopy to allow the measurements of nanostructures under extreme environments, such as ultra-high pressure, ultra-strong magnetic field, extreme low-temperature, is desirable to find/address more and more fundamental questions, about electron-electron correlation, excitonic effects and electron-phonon interactions, etc., and the new physics in nanostructures.

Abstract

Compton scattered X-rays carry fingerprints of the electron momentum distribution in the target material. The chapter starts with a historical overview of the Compton scattering technique and its development as a solid-state spectroscopy. This is followed by sections addressing theoretical underpinnings, instrumentation, and issues related to data handling of the Compton spectra. We conclude by presenting a few illustrative examples that highlight applications of the Compton scattering spectroscopy to metals, alloys, and other complex materials.

Key points

- Introduce the X-ray Compton scattering and related techniques as solid-state spectroscopies for probing ground-state electronic structures and Fermi surfaces of materials.
- Provide an overview of the theory of X-ray Compton scattering.
- Highlight the key role synchrotron light sources are playing in advancing the Compton scattering technique, including the development of the magnetic Compton scattering technique based on using circularly polarized light for probing spin-dependent properties of materials.
- Provide illustrative examples of the applications of the Compton scattering techniques, including their application as an advanced characterization tool for investigating functional materials such as the Li-ion battery materials.

Nomenclature

$B(r)$	Reciprocal form factor (–)
c	Speed of light (ms^{-1})
e	Charge of the electron (C)
E_0	Energy of incident photon ($\text{kg m}^2 \text{s}^{-2}$)
E_1	Energy of scattered photon ($\text{kg m}^2 \text{s}^{-2}$)
E_c	Energy at top of Compton profile ($\text{kg m}^2 \text{s}^{-2}$)
E_F	Fermi energy ($\text{kg m}^2 \text{s}^{-2}$)
h	Planck's constant ($\text{kg m}^2 \text{s}^{-1}$)
$\hbar$	Planck's constant/ 2π ($\text{kg m}^2 \text{s}^{-1}$)
J	Compton profile ($\text{kg}^{-1} \text{m}^{-1} \text{s}$)
k	Wave vector (m^{-1})
k_0	Momentum of incident photon (kg ms^{-1})
k_1	Momentum of scattered photon (kg ms^{-1})

[☆]*Change History:* September 2022. B Barbiellini and A Bansil have prepared the update. The new Fig.12 has been added. The Section “Comparison with Theory” has been expanded. Key points, Conclusion and References have been added. Minor stylistic improvements have been implemented throughout the text.

K	Reciprocal lattice vector (m^{-1})
m	Electronic rest mass (kg)
n	Occupation function (–)
p_0	Initial momentum of electron (kg m s^{-1})
p_1	Momentum of recoil electron (kg m s^{-1})
p_x, p_y, p_z	Components of electron momentum (kg ms^{-1})
p_F	Fermi momentum (kg m s^{-1})
P_s, P_1	Stokes parameters (–)
q	Scattering vector (m^{-1})
r_0	Classical electron radius (m)
$t_{1/2}$	Radioactive half-life (s)
Z	Total number of electrons (–)
α, α_0	Emission angle of recoil electron (rad)
β	Sample orientation (rad)
λ	Wavelength (m)
ν	Frequency (s^{-1})
ρ	Momentum density ($\text{kg}^{-3} \text{m}^{-3} \text{s}^3$)
σ	Cross section (m^2)
ϕ	Scattering angle (rad), crystal wave function ($\text{m}^{-3/2}$)
χ	Momentum wave function ($\text{kg}^{-3/2} \text{m}^{-3/2} \text{s}^{3/2}$)
ψ	Wave function ($\text{m}^{-3/2}$)
Ω	Solid angle (sterrad)
ε_0	Initial energy of electron ($\text{kg m}^2 \text{s}^{-2}$)
ε_1	Energy of recoil electron ($\text{kg m}^2 \text{s}^{-2}$)

Introduction

“Compton scattering” (Cooper et al., 2004) refers to a collision between a photon and a charged particle, often an electron, in which the photon loses a substantial fraction of its energy. The use of words “photon” and “collision” suggests a corpuscular nature of light, that is, that light may be viewed as a stream of particles with well-defined energies and momenta. The first indications that light can lose a part of its energy when scattered in this manner appeared at the beginning of the twentieth century. Convincing evidence was provided by the pioneering experiments in the 1920s by Arthur Compton after whom the effect has been named.

This was not the first time the suggestion had been made that light may behave as a particle. The photoelectric effect, in which a material irradiated by light can be seen to emit electrons, was earlier explained by Einstein by postulating that light of frequency ν consists of particles called light quanta (and later photons), each with energy $h\nu$, where h is Planck’s constant. For a given material, the photoemitted electrons possess energies, which depend on the frequency (or equivalently the wavelength, $\lambda = c/\nu$, where c is the speed of light), but not on the intensity of the incident light. Above a certain wavelength no electron emission is possible, as is observed to be the case, because a photon does not carry enough energy to overcome the binding energy of the electron to the material. Compton scattering, which views the photon-electron scattering to behave rather like billiard balls colliding with other billiard balls, thus reinforced Einstein’s explanation of the photoelectric effect.

An outline of this chapter is as follows. The following section gives an overview of the theory of Compton scattering. The equations for energy and momentum transfer and the cross section for the Compton scattering process are given. Various forms of Compton scattering are discussed: (1) Compton scattering from the charge distribution of electrons in a material; (2) magnetic Compton scattering; and (3) ($\gamma, e\gamma$) scattering, in which additional information is obtained by measuring the properties of the recoil electron in addition to those of the scattered photon. The third section addresses issues of instrumentation. In keeping with current trends, the emphasis is on experiments using synchrotron radiation facilities around the world, which provide bright sources of X-rays. The fourth section touches upon the effect of multiple scattering of a Compton scattered photon within the sample, which complicates the interpretation of data. The fifth section turns to methods of analyzing Compton scattering data. In those cases where an adequate dataset is available, one can in principle obtain the three-dimensional momentum density of the many-body electronic ground state of the material. Much insight has been gained into the electronic structure and bonding properties in wide classes of materials via comparisons of measured Compton scattering data with the corresponding ab initio computations. The last section concludes with a presentation of a few illustrative examples of such comparisons.

Theory

Consider first a collision between a photon and a stationary electron in free space. The incident photon has momentum $\mathbf{k}_0$ and energy $E_0 = |\mathbf{k}_0|c$. As a result of the collision, the electron recoils with momentum $\mathbf{p}_1$ and relativistic energy $\varepsilon_1 = [(p_1c)^2 + m^2c^4]^{1/2}$, while the momentum and energy of the scattered photon are $\mathbf{k}_1$ and $E_1 = |\mathbf{k}_1|c$, respectively. Energy and momentum conservation laws then yield

Fig. 1 Momentum conservation diagram for Compton scattering of an incident photon of momentum k_0 from a free electron at rest. k_1 is the momentum of the scattered photon, q the scattering vector, and ϕ the scattering angle.

Fig. 2 Momentum conservation diagram for Compton scattering of an incident photon of momentum k_0 from an electron with momentum p_0 . Upon recoiling, the electron has a momentum p_1 . The initial momentum p_0 is typically much smaller than p_1 .

$$\varepsilon_1 + E_1 = E_0 + mc^2 \quad (1)$$

$$p_1 + k_1 = k_0 \quad (2)$$

Eq. (2) shows that the momentum gained by the recoiling electron, $p_1 = k_0 - k_1 \equiv \hbar q$, is the same as the momentum lost by the photon, which, after division by $\hbar$, is called the scattering vector q (Fig. 1). Eliminating the electron momentum p_1 from Eqs. (1) and (2) gives

$$E_0 - E_1 = \frac{E_0 E_1}{mc^2} (1 - \cos \phi) \quad (3)$$

Recalling the relation $\lambda = hc/E$ for photons, this can be written as

$$\lambda_1 - \lambda_0 = \frac{h}{mc} (1 - \cos \phi) \quad (4)$$

The quantity $h/mc \sim 0.00243$ nm, called the Compton wavelength of the electron, is the natural unit of length in quantum electrodynamics. The shift in wavelength is seen from Eq. (4) to be independent of the energy of the incident photon. Therefore, this shift can be more easily detected by using high-energy radiation since the percentage change in wavelength is then larger. Eq. (3) can also be rewritten as

$$E_1 = \frac{E_0}{1 + (E_0/mc^2)(1 - \cos \phi)} \quad (5)$$

This equation shows that for X- or γ -rays of energy E_0 comparable to $mc^2 \sim 511$ keV, the energy loss at large scattering angles ϕ is a substantial fraction of the initial energy E_0 .

It is important to note that the energy conservation (Eq. (1)) neglects changes in the potential energy of the system, that is, the potential energy of the electron is assumed to be the same before and after the collision. In scattering from atoms, molecules, and solids, this approximation is valid only if the energy transferred in the scattering process is much larger than the relevant binding energies involved. Moreover, for high energy transfers, the scattering process is a fast one in that the duration of the interaction is too short for the system to rearrange itself. This is called the “impulse approximation,” and it is at the heart of much of the interpretation of the Compton scattering spectra from materials (Kaplan et al., 2003). In the deeply inelastic regime, where the “impulse approximation” is valid, Compton scattering provides a direct probe of the many-body ground state of the electronic system.

In the more realistic case of a moving electron with initial momentum p_0 and energy $\varepsilon_0 = [(p_0 c)^2 + m^2 c^4]^{1/2}$, the energy and momentum conservation conditions are

$$\varepsilon_1 + E_1 = \varepsilon_0 + E_0 \quad (6)$$

$$p_1 + k_1 = p_0 + k_0 \quad (7)$$

The scattering vector (Fig. 2) once again is $\hbar q \equiv k_0 - k_1 = p_1 - p_0$. Here, ε_0 and ε_1 cannot be eliminated simultaneously from Eqs. (6) and (7) to obtain an equation involving just the photon kinematics. However, elimination of p_1 leads to the expression

$$(E_0 - E_1)(\varepsilon_0 + \varepsilon_1) = (\hbar^2 q^2 + 2\hbar p_0 \cdot q)c^2 \quad (8)$$

Substituting $\varepsilon_0 = \varepsilon_1 = mc^2$ in Eq. (8), one obtains the useful nonrelativistic relation

$$E_0 - E_1 = \frac{\hbar^2 q^2}{2m} + \frac{\hbar \mathbf{p}_0 \cdot \mathbf{q}}{m} \quad (9)$$

The term $\hbar^2 q^2 / 2m$ is called the Compton shift, while the term $\hbar \mathbf{p}_0 \cdot \mathbf{q} / m$ has the character of a Doppler shift in that this term is proportional to the velocity component of the electron along the direction of $\mathbf{q}$. It is customary to choose p_z as the component of the initial electron momentum along the scattering vector so that $p_z = \mathbf{p}_0 \cdot \mathbf{q} / q$. If $p_z = 0$, then Eq. (9) becomes

$$E_0 - E_C = \frac{\hbar^2 q^2}{2m} \quad (10)$$

where E_C is the energy corresponding to the top of the Compton profile.

In the relativistic case Eq. (8) immediately yields

$$p_z = \frac{(E_0 - E_1)(\varepsilon_0 + \varepsilon_1) - \hbar^2 q^2 c^2}{2\hbar q c^2} \quad (11)$$

The scattering vector squared is

$$\begin{aligned} \hbar^2 q^2 &= k_0^2 + k_1^2 - 2k_0 k_1 \cos \phi \\ &= (E_0^2 + E_1^2 - 2E_0 E_1 \cos \phi) / c^2 \end{aligned} \quad (12)$$

Substituting (12) into (11), one obtains

$$p_z = \frac{(E_0 - E_1)\varepsilon_0 - E_0 E_1 (1 - \cos \phi)}{c \sqrt{E_0^2 + E_1^2 - 2E_0 E_1 \cos \phi}} \quad (13)$$

The width of the Compton profile is very narrow compared with E_C so that $E_C \approx E_1$, and one can use the leading order nonrelativistic approximation $\varepsilon_0 = mc^2$ to obtain the following equation:

$$\frac{p_z}{mc} \approx \frac{E_0 - E_1 - (E_0 E_1 / mc^2)(1 - \cos \phi)}{\sqrt{E_0^2 + E_1^2 - 2E_0 E_1 \cos \phi}} \quad (14)$$

This expression allows one to convert the energy scale of the Compton profile to a momentum scale. Conventionally, a minus sign is added to the left-hand side of (13) and (14), so that positive values of p_z correspond to the high-energy side of the profile. Notice also that the energy and momentum of the electron do not occur on the right-hand side of Eq. (14). In a typical Compton scattering experiment the kinematics of the recoil electron is not measured, so that the data are in effect integrated over the p_x - and p_y -components and p_z is the only electron momentum component measured.

The double differential scattering cross section for spin-dependent Compton scattering from a material containing a collection of moving electrons is (Cooper et al., 2004)

$$\frac{d^2 \sigma}{d\Omega dE_1} = (e^2 / mc^2)^2 (m / 2\hbar q) (E_1 / E_0) \times \{f(p_z) + (\cos \phi - 1) P_c \hat{\sigma} \cdot (\mathbf{k}_0 \cos \phi + \mathbf{k}_1) / mc\} J_{\text{mag}}(p_z) \quad (15)$$

where

$$f = 1 + \cos^2 \phi + [(E_0 - E_1) / mc^2] (1 - \cos \phi) + P_1 \sin^2 \phi \quad (16)$$

and P_c and P_1 denote the Stokes parameters which give the degree of circular and linear polarization, respectively, of the incident beam, $\hat{\sigma}$ is a unit vector along the direction of magnetization, and e^2 / mc^2 is the classical electron radius r_0 . Eq. (15) is valid at low energies, but at high energies the factor $m / 2\hbar q$ should be replaced by the more accurate expression

$$m / 2\hbar q [1 + E_0 / mc^2 (1 - \cos \phi)]$$

Due to the presence of the factor $(\mathbf{k}_0 \cos \phi + \mathbf{k}_1) / mc$, the magnetic part of the cross section increases with the photon energy.

The first term in the cross section of Eq. (15) is proportional to the so-called Compton scattering profile $J(p_z)$ due to charge scattering, which is defined as the projection of the total ground-state momentum density $\rho(\mathbf{p}) = \rho^\uparrow(\mathbf{p}) + \rho^\downarrow(\mathbf{p})$ onto the scattering vector $\mathbf{q}$ which was chosen as the z -axis, or, in other words,

$$J(p_z) = \iint [\rho^\uparrow(\mathbf{p}) + \rho^\downarrow(\mathbf{p})] dp_x dp_y \quad (17)$$

Here, $\rho^{\uparrow(\downarrow)}(\mathbf{p})$ denotes the momentum density of electrons with spin up (down) in a magnetic material. In a nonmagnetic material, of course $\rho^\uparrow(\mathbf{p}) = \rho^\downarrow(\mathbf{p})$. The momentum density, which is the probability distribution of electrons in momentum space, is given as (Barbiellini and Bansil, 2001)

$$\rho(\mathbf{p}) = \sum_i n_i |\chi_i(\mathbf{p})|^2 \quad (18)$$

where

$$\chi_i(\mathbf{p}) = (2\pi\hbar)^{-3/2} \int \psi_i(\mathbf{r}) e^{-i\mathbf{p}\cdot\mathbf{r}/\hbar} d\mathbf{r} \quad (19)$$

is the Fourier transform of the wave function $\psi_i(\mathbf{r})$ and the summation runs over all (spin-dependent) states i . A property of the Fourier transform is that $\psi_i(\mathbf{r})$ and $\chi_i(\mathbf{p})$ weight inverse regions of configuration space: the valence electrons, which tend to lie farther away from the nuclei contribute to $\chi_i(\mathbf{p})$ at low momenta, whereas the tightly bound core electrons contribute at higher momenta. Also, since $\chi_i(\mathbf{p})$ is the Fourier transform of $\psi_i(\mathbf{r})$, it contains the same fundamental information as $\psi_i(\mathbf{r})$. Thus, the momentum density describes the electronic system as well as the more familiar charge density. The occupation number n_i gives the number of electrons populating the i th state. In the absence of correlations between the electrons, $n_i = 1$ for an occupied state and $n_i = 0$ when the state is empty. Integrating the Compton profile $J(p_z)$ over p_z is equivalent to integrating the momentum density $\rho(\mathbf{p})$ over the entire $\mathbf{p}$ -space, which from the properties of the Fourier transform is the same as the integral of the real-space charge density. But the integral of the charge density (appropriately normalized) obviously is the number of electrons Z per formula unit. This observation makes it possible to normalize the Compton profile on an absolute scale. However, it is emphasized that the simple relationship given by Eq. (17) between the Compton profile and the electron momentum density (EMD) only exists by the grace of the impulse approximation (Kaplan et al., 2003).

The second term in formula (15), which can be measured due to the circular polarization P_c of the incident radiation, contains the magnetic Compton scattering profile:

$$J_{\text{mag}}(p_z) = \iint [\rho^\uparrow(\mathbf{p}) - \rho^\downarrow(\mathbf{p})] dp_x dp_y \quad (20)$$

which, like the $J(p_z)$ of Eq. (17), is a projection along p_z , except that $J_{\text{mag}}(p_z)$ involves the difference (rather than the sum) of the up- and down-spin momentum densities. $J_{\text{mag}}(p_z)$ is thus related to the ground-state momentum distribution of the electrons with unpaired spin. The magnetic term in the cross section (15) is typically smaller than the charge scattering term proportional to $J(p_z)$ by a few orders of magnitude. This is due firstly to the factor of $(\mathbf{k}_0 \cos \phi + \mathbf{k}_1)/mc \approx E/mc^2$, since the photon energy is usually only a fraction of mc^2 , and secondly because the integral of the magnetic Compton profile $\int J_{\text{mag}}(p_z) dp_z$ equals the number of electrons with unpaired spin, which is much less than the total number of electrons Z . The magnetic effect, however, increases with photon energy. It is to be noted that, in contrast to the scattering of polarized neutrons, magnetic Compton scattering only involves the electron spin, and does not depend on the orbital moment.

It is helpful to consider the momentum density of the noninteracting free-electron gas at 0 K. In this case, electrons occupy all available energy levels up to the Fermi energy E_F . Since $E = p^2/2m$, the occupied states fill a sphere in momentum space, the Fermi sphere, of radius $p_F = \sqrt{2mE_F}$, which is called the Fermi momentum. Thus, $n_i = 1$ and $n_i = 0$ inside and outside the Fermi sphere, respectively. It is then easily shown from Eq. (17) that the Compton profile is given by the area of the slice of the Fermi sphere at $p = p_z$ (Fig. 3):

$$\begin{aligned} J(p_z) &= 2\pi(p_F^2 - p_z^2) & p_z \leq p_F \\ J(p_z) &= 0 & p_z > p_F \end{aligned} \quad (21)$$

which has the shape of an inverted parabola. The factor of 2 in $J(p_z)$ here accounts for the spin degeneracy of free-electron states. Eq. (21) describes the basic shape of $J(p_z)$ associated with the loosely bound conduction electrons in metals. The contribution of the more tightly bound core electrons varies smoothly and extends to much higher momenta, so that the total Compton profile

Fig. 3 Schematic Compton profile $J(p_z)$ for a hypothetical metal with two core electrons and one free conduction electron per atom. The parabolic contribution of the free electron is given by the area of the slice (for different p_z values) through the Fermi sphere of radius p_F as shown in the inset.

possesses the shape of an inverted parabola sitting on top of the broader core contribution (Fig. 3). The positions of the two kinks in $J(p_z)$ at $p_z = \pm p_F$ mark the Fermi momentum p_F . In a measured Compton profile these kinks will only appear as rapid changes in slope around the Fermi momentum because of finite experimental resolution. The width of the rapidly varying portion of the Compton profile is a direct result of the spreading of the electrons throughout the Fermi sphere due to Pauli's exclusion principle and the associated Fermi–Dirac statistics of electrons, which forbids more than one electron (of a given spin) to occupy any energy level.

In a real electron gas, electrons interact through Coulomb forces, so that electronic motions become correlated in the sense that an individual electron no longer moves independently of the positions of other electrons. The Coulomb interaction kicks some electrons out of the Fermi sphere, even at zero temperature, and in the process free-electron (noninteracting) states above the Fermi momentum become partially occupied at the expense of states inside the Fermi sphere. The occupation numbers thus become smaller than 1 below E_F and nonzero above E_F , and the momentum distribution becomes more spread out. This effect of electron correlations can be identified in experimental Compton scattering profiles.

In a crystal, electrons experience a periodic potential due to the presence of the underlying lattice. The energy spectrum of the crystal can be shown to consist of groups of levels or bands, where eigenstates within each band are characterized by the wave vector $\mathbf{k}$, which is restricted to lie within the first Brillouin zone. The crystal wave function $\phi_i(\mathbf{k})$ for the i th band for wave vector $\mathbf{k}$ contains momentum contributions not only at $\mathbf{p} = \hbar\mathbf{k}$, but also at momenta $\mathbf{p} = \hbar(\mathbf{k} + \mathbf{K})$, where $\mathbf{K}$ is any one of the group of reciprocal lattice vectors associated with the real space crystal lattice (there should be no confusion with the photon momenta $\mathbf{k}_0$ and $\mathbf{k}_1$ introduced earlier). The periodic potential thus has the effect of broadening the valence electron momentum distribution somewhat like the effect of electron correlations. Moreover, the Fermi surface breaks in the momentum density of the crystal will generally occur not only at the momenta p_F , but also at all the Umklapp images of the Fermi surface at momenta $p_F + \hbar\mathbf{K}$ with appropriate weights.

The twofold integration of $\rho(\mathbf{p})$ in Eq. (17) reflects the fact that in a standard Compton experiment, only the characteristics of the incoming and outgoing photons are measured and those of the recoiling electrons are ignored. It is obviously attractive to devise a way of measuring the three-dimensional momentum density $\rho(\mathbf{p})$. This is possible if the kinematics of the recoil electron is measured in coincidence with that of the Compton scattered photon. This is referred to as a $(\gamma, e\gamma)$ experiment since here one measures the cross section for the process in which a γ -ray photon scatters into a photon and an electron. Fig. 4 clarifies the various momenta involved. The recoil electron is emitted at an angle α (this angle does not necessarily lie in the plane defined by $\mathbf{k}_0$, $\mathbf{k}_1$, and $\hbar\mathbf{q}$) with respect to the primary beam direction. The angle α_0 for an electron initially at rest is given by

$$\cot \alpha_0 = (1 + E_0/mc^2) \tan(\phi/2) \quad (22)$$

The components p_x and p_y of the initial electron momentum $\mathbf{p}_0$ cause the recoil electron to end up in solid angles closely around the direction α_0 , where it can be detected with the aid of a position-sensitive detector. As before, p_z can be determined from the Doppler broadening formula (13). Alternatively, one may measure the energy of the recoil electron by a time-of-flight method in coincidence with that of the photon. It should be emphasized that if the coincidence condition is not imposed, the energy distribution of the scattered photons as well as that of the recoil electrons is each proportional to the Compton profile. Only by observing the photon and the electron in coincidence does one obtain $\rho(\mathbf{p})$. Since electrons interact strongly with matter, $(\gamma, e\gamma)$ experiments require very thin samples in order to minimize the scattering of the recoil electrons.

A technique closely related to $(\gamma, e\gamma)$ scattering is $(e, 2e)$ scattering in which an incoming electron generates two outgoing electrons, the scattered and the recoiling one, and the kinematics of the two outgoing electrons is measured in coincidence. Electron scattering is even more of a problem in such an experiment. Finally, inverse Compton scattering in which a photon takes up energy by collision with an energetic electron plays a role in astrophysics.

Instrumentation

In its simplest form, a Compton scattering experiment involves a source of X- or γ -rays of a well-defined energy (or at least with a strong monochromatic component in its energy spectrum), a sample, an energy analyzer, and a detector to register the scattered radiation (Fig. 5). Along its path, the radiation is narrowly collimated by systems of parallel Soller slits to achieve an accurate

Fig. 4 Momentum conservation diagram for $(\gamma, e\gamma)$ scattering, where various momenta have been defined previously in Figs. 1 and 2. α_0 refers to the limiting case where the electron is initially at rest.

Fig. 5 Schematic setup of an X-ray Compton scattering experiment.

definition of the various angles and thus of the energy of the scattered radiation. The scattered photons are energy-analyzed by Bragg reflection from an analyzing crystal (usually LiF or Si) and detected with the aid of a scintillation detector. In such a setup, the Compton profile is obtained via a step-by-step energy scan, and the experiment therefore suffers from long data collection times and possible instabilities due to temperature variations, electronic drift, and other effects. Improvement is achieved by replacing the analyzer-detector combination with a high-resolution high-purity or lithium-drifted germanium solid-state detector, which registers the entire spectrum simultaneously, at the expense, however, of resolution.

When an X-ray tube is used, the energy of the incoming radiation is limited to several tens of keV (Mo or Ag anode) or at most to ~ 60 keV for the $K\alpha_1$ line of a tungsten anode. The flux from X-ray tubes is often too low to allow the use of a primary monochromator, and the scattered spectrum therefore consists of contributions from the $K\alpha_1$ and $K\alpha_2$ lines, in addition to other parts of the spectrum, which complicates the interpretation of the measured profiles. Over the years, the count rates have improved with the development of more powerful X-ray tubes, sometimes with rotating anodes, and the use of large samples in combination with bent analyzing crystals, which focus the broad scattered beam onto the detector, thereby allowing radiation with a larger divergence angle to be used. Momentum resolutions for this type of setup vary between 0.15 and 0.5 a.u. full-width-at-half-maximum (1 a.u. of momentum equals 1.9929×10^{-24} kg m s $^{-1}$), depending on the details of the instrumental design.

The relatively low energy of the radiation provided by X-ray tubes limits Compton experiments to materials with low Z values, since at these energies Compton scattering increases as Z while the competing photoelectric absorption increases as Z^5 . Also, at low photon energies, the impulse approximation, which requires the energy transferred in the scattering process to be large compared to the binding energies involved, ceases to be valid for high Z atoms. Higher-energy radiation is needed to circumvent these limitations. γ -ray sources using radioactive isotopes offer the advantage of providing radiation of a high, single energy, and often possess a long half-life $t_{1/2}$. Examples include ^{241}Am (60 keV, $t_{1/2} = 425$ years), ^{198}Au (412 keV, 2.7 days), and ^{137}Cs (667 keV, 30 years). In combination with a solid-state detector, these sources allow the simultaneous detection of the entire Compton scattered spectrum in an apparatus without moving parts. Shielding is a serious problem at these high energies and limits the maximum scattering angle that can be used. An annular shape of the source with the scattered beam passing through the center of the ring can offer a solution. Scattering in the source itself should be kept low since it produces a tail at the low-energy side of the Compton line, which must be corrected for in data-handling procedures. For this purpose, a source material with a high specific activity should be used. The best momentum resolution of ~ 0.40 a.u. that can be achieved with γ -ray sources is substantially worse than that of a high-resolution X-ray setup using an analyzing crystal. This is an important consideration in some investigations since a high momentum resolution of ~ 0.1 a.u. or better is generally needed for observing Fermi surface signatures in the Compton spectra.

The most versatile source of X-rays is synchrotron radiation, which is produced by the acceleration of charged particles, most commonly electrons, going around a circular orbit. The synchrotron radiation beam has a small angular divergence and is emitted in the forward direction by the orbiting particles, rather like the searchlight beam in a lighthouse. Photons emitted in the orbital plane are linearly polarized, while those emitted above and below this plane are circularly polarized. The energy range over which an intense flux of linearly or circularly polarized photons is produced can be extended by increasing the acceleration of the orbiting particles over a small portion of their trajectory. This can be achieved with the aid of a suitably designed insertion device, an “undulator” or “wiggler,” which introduces a small wiggle in the particle orbit. In a symmetric wiggler the two directions of circular polarization cancel, so the insertion device should contain a certain degree of asymmetry. Since the energy spectrum of synchrotron radiation is “white,” a monochromator must be used to “cut” a monochromatic slice from this spectrum. Perfect Si or Ge single crystals with a rocking curve of width comparable to the beam divergence are often used as monochromators. These must be cooled to maintain stability in the presence of an intense heat load of several 100 W to a few kW to which they are exposed. The scattered beam is analyzed using a curved analyzing crystal and focused onto a detector. The high intensity of radiation may in some cases cause overloading of the detector electronics. Fig. 6 shows a Compton setup in used at ESRF in Grenoble, France. Another setup suitable for heavy element materials is available at the BL08W beamline at the SPring-8 synchrotron facility (Japan) (Sakurai and Ito, 2004).

Typical synchrotron fluxes at the sources used for Compton scattering vary between 10^{10} and a few times 10^{13} photons s^{-1} , while initial photon energies range from 10 keV to >250 keV. Such fluxes are sufficiently high for carrying out several different types of experiments. For example, using unpolarized or linearly polarized light, conventional Compton profiles for electronic structure studies may be measured with a resolution of 0.10–0.15 a.u. or better. If the initial radiation is circularly polarized, the presence of the spin-dependent term in the scattering cross section of Eq. (15) enables one to measure the magnetic momentum density of electrons with unpaired spin in ferromagnetic or ferrimagnetic media (since Compton scattering is an incoherent process, no magnetic effect is observed in antiferromagnetic materials). Since the synchrotron beam decays exponentially in time, the magnetization of the sample or the circular polarization (helicity) of the photons should be reversed every 10 s or so in the pattern (+ – +). A high circular polarization is achieved at the expense of a high flux. In view of the smallness of the magnetic effect and the importance of good statistics, resolution has therefore to be traded against intensity and much of the currently existing magnetic Compton scattering work is limited to a resolution of ~ 0.4 a.u. or worse.

Finally, the way is open to $(\gamma, e\gamma)$ spectroscopy. As discussed in the second section, by measuring the recoiling electron in coincidence with the scattered photon, it is possible to determine the three-dimensional momentum density $\rho(\mathbf{p})$ of the electrons in a material. $(\gamma, e\gamma)$ measurements are only feasible with an intense flux of high-energy (about 150 keV) photons. Measurements of $\rho(\mathbf{p})$ on very thin (17–25 nm thick) graphite samples have been performed in this way with a momentum resolution of 0.60 (0.85) a.u. in the $p_z(p_x)$ -direction (Sattler et al., 2001). A better resolution has been obtained with a time-of-flight spectrometer. In cases where the extremely low cross section of the process makes it necessary to integrate over the energy distributions of the recoil electron as well as the scattered photon, one is left with information only on the perpendicular components p_x and p_y of the initial electron momentum. The quantity measured is then a once-integrated, two-dimensional distribution of the EMD like a two-dimensional angular correlation distribution of photons from positrons annihilating in a solid (Barbiellini et al., 2003).

Multiple scattering

Multiple scattering refers to events in which the Compton scattered photon is further scattered one or more times within the sample before it escapes to the detector. The presence of multiple scattering events in the measured Compton profile complicates the analysis of the data. Generally, the multiple scattering contribution tends to broaden the profile somewhat, but its detailed energy dependence on sample geometry and thickness is complex. The effect can be reduced by choosing a thin sample, but that also results in a reduction in the intensity of the primary Compton scattering events of interest. Attempts to measure a Compton profile for various thicknesses followed by extrapolation to zero thickness suffer from the nonlinear dependence of multiple scattering on sample thickness. The most reliable results are obtained using an iterative Monte Carlo approach to simulate the effect of multiple scattering under the specific experimental conditions.

Fig. 6 Drawing of the scanning spectrometer at ESRF, Grenoble, France. The beam reflected by the monochromator (M) is collimated by the entrance slit, and the beam scattered by the sample (S) is collimated by the aperture slit. The sample, analyzer crystal (A), and the detector slit lie on the dashed circle. The detector (D) is an NaI scintillation counter. A Si-diode (Si-d) and a Ge detector (SSD) are used for monitoring. The arrows indicate translations and rotations of the analyzer and detector. The monochromator part of the figure is scaled down by a factor of 10. Courtesy of V Honkimaki.

Data analysis

Although all electrons contribute equally to the Compton profile, one is usually interested in the properties of the smaller group of valence electrons, which are mainly responsible for bonding as they undergo substantial changes when the material is formed by bringing the atoms together. The tightly bound core electrons are relatively unaffected and their contribution to the Compton profile is isotropic. One way to highlight the contribution of valence electrons in analyzing Compton data is to consider differences $\Delta J(p_z)$ between the Compton profiles measured along various pairs of directions of the scattering vector from an oriented monocrystalline specimen, for example, $\Delta J(p_z) \equiv [J_{100}(p_z) - J_{110}(p_z)]$, for the directional difference between the [100] and [110] profiles. The advantage is that the contributions from core electrons, background, and correlation effects (to the extent these are isotropic) cancel in $\Delta J(p_z)$ and the anisotropies related to the valence electrons become clearer.

As seen in the second section, the Compton profile in a crystal generally contains kinks (with appropriate weights) at the Fermi momentum p_F as well as at the images of the Fermi surface at higher momenta induced by the periodic crystalline potential. These kinks originate from breaks in the underlying three-dimensional momentum density $\rho(\mathbf{p})$. They can be made more clearly visible by considering the first or even the second derivative of the Compton spectrum.

Relation (17), which defines the Compton profile $J(p_z)$ as a two-dimensional integral of the momentum density $\rho(\mathbf{p})$, may alternatively be viewed as an integral equation for determining the three-dimensional function $\rho(\mathbf{p})$. The problem can then be formulated as one of “inverting” relation (17) or “reconstructing” $\rho(\mathbf{p})$ from a given set $J_\beta(p_z)$ of profiles corresponding to different orientations (scattering vectors) β of a monocrystalline sample. For this purpose, two approaches are commonly used. One is to expand $\rho(\mathbf{p})$ into a series of appropriately chosen directional harmonics. These can be the spherical harmonics, but often the crystal lattice possesses an inherent point symmetry, in which case harmonics of a higher symmetry (called lattice harmonics) are advantageous to use since one needs a smaller number of such harmonics. The expansion coefficients in this series can be expressed as Hankel or Bessel transforms of linear combinations of the set of profiles $J_\beta(p_z)$. This method is particularly useful if the momentum density $\rho(\mathbf{p})$ and the Fermi surface are not too far from being spherical. Methods of the second category disregard the point symmetry and solve the problem by Fourier transform techniques. The reconstruction itself can be performed in either the $\mathbf{p}$ - or the $\mathbf{r}$ -space. In the latter case one considers the reciprocal form factor $B(\mathbf{r})$ by taking the Fourier transform of $\rho(\mathbf{p})$ (Cooper et al., 2004):

$$B(\mathbf{r}) = \int \rho(\mathbf{p}) \exp(i\mathbf{p} \cdot \mathbf{r} / \hbar) d\mathbf{p} \quad (23)$$

from which it is easily shown that

$$B(z) = \int_{-\infty}^{\infty} J(p_z) \exp(ip_z z / \hbar) dp_z \quad (24)$$

Thus, the one-dimensional Fourier transform of a Compton profile with the scattering vector along a given direction β equals $B_\beta(\mathbf{r})$ along a ray in that same direction in $\mathbf{r}$ -space through the origin. $B_\beta(\mathbf{r})$ can thus be obtained along different rays in $\mathbf{r}$ -space from the set of Compton profiles $J_\beta(p_z)$. It is then a simple matter to find the three-dimensional function $B(\mathbf{r})$ via interpolation, followed by an inverse Fourier transformation of $B(\mathbf{r})$,

$$\rho(\mathbf{p}) = (2\pi\hbar)^{-3} \int B(\mathbf{r}) \exp(-i\mathbf{p} \cdot \mathbf{r} / \hbar) d\mathbf{r} \quad (25)$$

to find the momentum density $\rho(\mathbf{p})$.

A useful theorem (the “Lock-Crisp-West” (LCW) theorem) connects the momentum density $\rho(\mathbf{p})$ with the occupation density $n(\mathbf{k})$, which represents the number of filled electron states at wave vector $\mathbf{k}$:

$$n(\mathbf{k}) = \sum_{\mathbf{K}} \rho(\hbar\mathbf{k} + \hbar\mathbf{K}) \quad (26)$$

where the summation is over the reciprocal lattice vectors $\mathbf{K}$. The occupation density $n(\mathbf{k})$ is a periodic function of $\mathbf{k}$, that is, $n(\mathbf{k}) = n(\mathbf{k} + \mathbf{G})$ for any reciprocal vector $\mathbf{G}$. The theorem states that the occupation density at wave vector $\mathbf{k}$ is obtained by folding the momentum density at all corresponding points $\mathbf{p} = \hbar(\mathbf{k} + \mathbf{K})$ in the higher Brillouin zones back into the first zone.

Comparison with theory

The methods discussed in the preceding section have all been used extensively in analyzing Compton data. Insight into wide classes of materials has been gained via comparisons between experimental Compton spectra and the corresponding first-principles electronic structure computations. In this connection, many reliable techniques based on the local (spin) density approximation of density-functional theory have been developed for treating crystalline systems during the last few decades such as the (linearized) augmented plane wave (LAPW) method, the linearized muffin-tin orbital (LMTO) method, and the Korringa-Kohn-Rostoker (KKR) method (Cooper et al., 2004). The KKR method is based on the use of multiple scattering theory and possesses the advantage that it can be generalized straightforwardly to treat the electronic structure and momentum densities in substitutionally disordered (random solid solution) phases of alloys within the KKR-CPA scheme (Bansil, 1979a; Bansil, 1979b; Bansil et al., 1981;

Fig. 7 (a) Measured (. . .) and computed (—) Compton profile along the three principal symmetry directions of lithium. (b) First derivatives of the profiles. Theoretical profiles are shown with (—) and without (---) resolution broadening of 0.12 a.u. The structures marked a_1 – a_3 and b_1 – b_3 are Fermi surface breaks. The free-electron result is given for the [111] case. (c) Second derivatives of profiles. Arrows mark the theoretical Fermi radii. Bansil et al., 1999; Mijnenands and Bansil, 1990). A few illustrative examples of comparison between theory and experiment are presented now. These results will also serve to highlight some of the general features of the Compton spectra that have been discussed throughout this chapter.

Fig. 7 (Sakurai et al., 1995) shows the Compton profiles for lithium (Li). The measured and computed Compton profiles for the scattering vector lying along three high-symmetry directions are shown in Fig. 7a. All profiles have been normalized so that the area under each of the profiles equals the number of electrons (three) in Li. The first derivatives of the profiles in Fig. 7b show that unbroadened theory curves (long dashes) contain breaks at Fermi radii (a_1 – a_3) and one set of associated images at $p_F + \hbar K$ (b_1 – b_3). The resolution broadening of 0.12 a.u. (full-width-at-half-maximum) washes out the breaks b_1 – b_3 as seen from the solid lines. The first derivative for the free-electron profile of Eq. (21), shown for reference only along the [111]-direction by the dot-dashed line, makes it clear that the momentum density in even a relatively simple system such as Li is modified significantly from the free-electron behavior due to solid-state effects. In addition, note how differences in the results for the three directions, that is, the anisotropy of the profile, are more evident in Fig. 7b compared to Fig. 7a. The actual Fermi surface radii a_1 – a_3 are more easily

Fig. 8 Directional difference profiles for the disordered alloy $\text{Ni}_{75}\text{Cu}_{25}$. The experimental ($\blacklozenge$) results are compared with theoretical profiles with (—) and without (---) the experimental resolution of 0.4 a.u. determined from the second derivatives of Fig. 7c and are denoted in the theory curves by arrows. The Fermi surface of lithium is a distorted sphere, somewhat elongated along the $\langle 110 \rangle$ directions. The agreement between theory and experiment is good overall, although the theoretical distribution and particularly the Fermi surface breaks are broader in the experiment. This discrepancy reflects the residual electron correlation effects that are not treated accurately in the conventional band theory picture underlying the computations of Fig. 7 (Sakurai et al., 1995; Stutz et al., 1999; Tanaka et al., 2001; Matsumoto et al., 2001; Kwiatkowska et al., 2006; Hämäläinen et al., 1996; Huotari et al., 2000).

Fig. 8 (Bansil et al., 1998) considers directional anisotropies with the example of an alloy. The results here are for a solid solution of $\text{Ni}_{75}\text{Cu}_{25}$. The maximum value of the anisotropy $\Delta J(p_z)$ is typically one to two orders of magnitude smaller than the Compton peak intensity. The experimental data in Fig. 8 were taken using a γ -ray source with a momentum resolution of 0.4 a.u. (FWHM), under which all Fermi surface signatures in the data are essentially washed out. Despite some differences in detail, the undulations in $\Delta J(p_z)$ are similar in theory and experiment. The presence of oscillations in $\Delta J(p_z)$ extending to rather high momenta is indicative of interactions in the solid state (Bansil et al., 1998).

Fig. 9 (Matsumoto et al., 2001) takes up an example where a reconstruction technique has been applied to obtain the Fermi surface of the alloy Al-3 at.%Li. Here nine Compton profiles with scattering vectors in the (110) plane were measured and Fourier-transformed to obtain a projection of the momentum density $\rho(\mathbf{p})$ onto the (110) plane. Using the LCW folding procedure of (26) over a selected set of K 's then yields the projected image of the Fermi surface shown in Fig. 9. The presence of the Fermi surface outside the indicated geometrical boundaries of the first Brillouin zone is clearly seen. The theoretical maps in the figure have been obtained from nine corresponding computed profiles following procedures which were identical to those used to treat the experimental data.

Fig. 9 Contour maps of the (a) theoretical and (b) experimental (1 1 0)-plane-projected occupation number densities for Al-3 at.%Li, obtained by LCW folding. Resolution broadening (0.12 a.u.) is included in the theory. The dashed lines mark the first Brillouin zone. The plus signs indicate high-density regions. Fig. 10 (Tanaka et al., 1993) presents the magnetic momentum density of the electrons with unpaired spin in iron. In this study Compton profiles were measured for 14 orientations of an iron single crystal. By reversing the magnetization, two profiles were obtained for each of the 14 orientations; their differences yielded 14 magnetic Compton profiles. The Fourier transforms of these 14 profiles were used to map the reciprocal magnetic form factor $B_{\text{mag}}(\mathbf{r})$ along the lines of Eq. (24). The inverse transform of (23) was then performed to obtain the magnetic momentum density $\rho_{\text{mag}}(\mathbf{p})$ of Fig. 10a, which is seen to display a large negative momentum density at low momenta. Fig. 10b depicts the corresponding theoretical results and shows a similar general behavior of the computed momentum density.

An example of a complex material is given in Fig. 11 (Li et al., 2004). The magnetic Compton profile from the double-layer manganite $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ for the scattering vector along the [110] direction is shown. Measurements were carried out at a temperature of 5 K under an external magnetic field of 7 T along [110]. The theoretical profile computed within the first-principles band theory picture is seen after resolution broadening (thick line) to be in good accord with experiments. The shape of the profile in Fig. 11 can be analyzed in terms of the reciprocal form factor $B(\mathbf{r})$ given by the one-dimensional Fourier transform of the profile, see Eq. (24). By interpreting $B(\mathbf{r})$ as the autocorrelation function of the ground-state wavefunction, one can obtain a handle on the shapes and occupancies of various magnetic orbitals in the system. In particular, the $B(\mathbf{r})$ along the [110] direction is found to display a distinct dip at around 0.1 nm; the value (B_{min}) of $B(\mathbf{r})$ at the minimum can be related to the occupancy of the $3d(x^2-y^2)$ molecular orbital involved in the Mn—O bonding as discussed in reference (Li et al., 2004). Studies such as those of Fig. 11 illustrate the ability of magnetic and non-magnetic Compton scattering to analyze the phase diagrams of complex materials (Barbiellini et al., 2009) as a function of doping.

Fig. 11 Experimental (●) and theoretical magnetic Compton profiles along [110] direction in the double layer manganite $\text{La}_{12}\text{Sr}_{18}\text{Mn}_2\text{O}_7$. Measurements were carried out at 5 K under a magnetic field of 7 T. The theoretical profile is shown with (—) and without (---) resolution broadening of 0.4 a.u. All profiles are normalized such that the area gives the measured magnetic moment of $3.4 \mu_B/\text{Mn}$ atom. The image has been obtained by subtracting the momentum density corresponding to $x = 0.4$ from that of $x = 0$. Reprinted figure with permission from Hafiz et al. (2021) *Nature* 594: 213; © Springer-Nature.

In fact, Compton scattering studies of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ single crystals have directly imaged the character of the doped holes in this high transition-temperature superconductor. At low doping levels, the O-2p character of the hole is much stronger than the Cu-3d character but at high doping levels the Cu-3d orbital becomes dominant (Sakurai et al., 2011). Along this line, Compton scattering has been used to study reduction-oxidation (redox) reactions in cathode materials for lithium batteries (Suzuki et al., 2015; Barbiellini et al., 2016; Hafiz et al., 2017), where the octahedron formed by a transition metal atom and six oxygen atoms plays a key role like the CuO_6 building block in the copper-oxide superconductors. Very recently, Compton scattering uncovered a new redox mechanism involving oxygen reduction in Li-rich cathodes (Hafiz et al., 2021) and yielded new insight into the nature of the transition-metal redox as well as oxygen redox processes and provided a visual image of the redox orbitals involved in the two cases via tomographic reconstruction. Fig. 12 illustrates the momentum density of the oxygen redox orbital in $\text{Li}_x\text{Ti}_{0.4}\text{Mn}_{0.4}\text{O}_2$. In this way, Compton scattering is providing a new spectroscopic window for in situ, in operando probing of redox orbitals in working batteries, and a novel pathway for rational design of improved battery materials.

Conclusion

This review discusses the X-ray Compton scattering and related techniques as solid-state spectroscopies for probing ground-state electronic structures and Fermi surfaces of materials. An overview of the theory of X-ray Compton scattering is provided. The key role

of synchrotron light sources in advancing the Compton scattering technique, including the development of the magnetic Compton scattering technique based on using circularly polarized light for probing spin-dependent properties of materials is highlighted. Illustrative applications of the Compton scattering techniques, including their application as an advanced characterization tool for investigating functional materials such as the Li-ion battery materials are presented.

Abstract

Interaction of laser light with natural acoustic phonons in materials can be used for non-destructive measurement of elastic parameters of materials. The Brillouin scattering technique is used for both basic research and applied efforts for all kinds of physical states: gases, liquids and solids. The article defines the scattering phenomenon itself, discusses the basic metrological elements and reviews the results of experimental work, mainly from the perspective of material research.

Key points

- Non-destructive materials characterization.
- Measurements of elastic properties of materials.
- Spectroscopy of acoustic phonons.
- Single acoustic phonon creation and annihilation.
- Light scattering of magnons in the hypersonic range of frequencies.

Introduction

Brillouin scattering (BLS), in its historical sense, is the inelastic scattering of light by acoustic phonons. It thus provides information on the elastic properties of the scattering medium and it has been used to study gases, liquids, crystals, polymers, glasses, semiconductors, nontransparent thin layers, and superlattices. BLS yields information similar to that obtained using ultrasonic techniques but it has certain advantages when dealing with small samples, reactive samples, or in cases where contact with a transducer poses experimental difficulties (e.g., high temperatures and pressures). The Fabry-Perot interferometer (FP) is, par excellence, the instrument of choice to achieve the 1–100 GHz resolution required in typical BLS experiments. Because of this, BLS has become synonymous for all experiments performed with an FP independent of whether the scattering is produced by acoustic phonons, by magnons, or by electronic states. Here we will use BLS in this broader context.

This article provides a brief historical review and a condensed description of the origin of the effect. Also, some key experimental aspects are briefly described. The emphasis of this article is to illustrate, via specific examples, the range of problems that can be investigated using BLS. This will include the determination of elastic constants with emphasis on its application under adverse experimental conditions (temperature, size and pressure), as well as its application to magnetic systems and electronic levels.

[☆]*Change History:* July 2022. T Blachowicz updated the text. The update modified only text and references. Mentioned about new results and ideas in the field providing adequate citations.

Brief history of BLS

The term Brillouin light scattering (BLS) was derived from the theoretical prediction made by L Brillouin in 1914 of a possible inelastic interaction between light and sound. The description of light-scattering experiments was published in his Ph.D. dissertation. A similar prediction was made independently in 1926 by L I Mandelstam. The first experiment was performed by E Gross in 1930. BLS spectroscopy developed rapidly in the early 1960s as lasers became available. The first light-scattering experiments in pure liquids were done by G B Benedek, et al. in 1964. The technique remained almost an academic curiosity until the multi-passed and later the tandem FP, both introduced by J Sandercock, enabled the weak Brillouin signals to be observed in the presence of the usually overwhelming intensity of the elastically scattered light. At that point, BLS became a powerful and versatile tool for material characterization. This article describes how it has made significant contributions to a wide range of problems in condensed matter physics.

Origin of BLS

Any excitation that produces a time-varying change in the polarizability of a medium (for a longitudinal sound wave this is related to the change in refractive index caused by the densification and rarefaction produced by the wave) interacts with electromagnetic radiation via the polarizability α . The polarization of the medium induced by the electromagnetic wave becomes

$$\mathbf{P}(\mathbf{r}, t) = [\langle \alpha \rangle + \delta \alpha(\mathbf{r}, t)] \mathbf{E}_0 e^{i(\mathbf{k} \cdot \mathbf{r} - \omega_0 t)},$$

and it can be shown that this leads to the re-radiation of electromagnetic waves with frequencies $\omega_0 \pm \omega_{phon}$. The origin of the polarizability changes ($\delta \alpha$) is different for different excitations: bulk phonons modulate the polarizability via elasto-optic effects (strain-induced changes in refractive index), surface phonons produce polarizability changes as the interface moves into and out of the vacuum (known as the ripple mechanism), and magnons interact via magneto-optic contributions.

Interference between the radiation emanating from throughout the sample leads to the condition that only excitations with wave-vector $\mathbf{q}$ that satisfy

$$\mathbf{q} = \mathbf{k}' - \mathbf{k},$$

where $\mathbf{k}$ and $\mathbf{k}'$ are the wave-vectors of the incident and scattered radiation, respectively, will produce scattered radiation. Since $\mathbf{k}$ and $\mathbf{k}'$ are determined by the directions of the incident and scattered radiation, it is clear from the above equation that in a given experiment only excitations with a fixed wave vector will be probed. This also makes it clear that the geometry chosen for the experiment is crucial for analyzing the resulting data.

Scattering geometries and frequency analysis

There are a number of scattering geometries that are often used in Brillouin experiments; these are shown schematically in Fig. 1. Not only does each scattering geometry select different q values but it is clear that geometries (a), (b) and (c) are only suitable for transparent materials while geometries (d) and (e) can be used even if the sample is not transparent. The (e) geometry is a variant of the back-scattering geometry (d). The magnitude of the wave vector probed in each geometry, calculated from the $\mathbf{q} = \mathbf{k}' - \mathbf{k}$ equation, is also indicated in Fig. 1. In these expressions $|\mathbf{k}| = 2\pi/\lambda$ (with λ the wavelength of the incident radiation, and n the refractive index of the medium). In opaque materials, only the component of q parallel to the surface is conserved so that the $\mathbf{q} = \mathbf{k}' - \mathbf{k}$ equation yields only the value of $\mathbf{q}$ in the surface plane $\mathbf{q}_s$. Typically, the choice of scattering geometry depends on the nature of the sample and the constraints of the experiment being performed; for example, cryostat, magnet, or furnace. In the laboratory, the incident radiation depicted in Fig. 1 is usually delivered by a laser. Since the frequency shifts are small, it normally requires a laser operating in a single longitudinal cavity mode. The scattered radiation is typically collected by a high quality lens (often a camera lens). Frequency analysis of the scattered light is accomplished using an Fabry-Perot interferometer. In all but a few cases, experiments rely on the high contrast provided by multi-passed and/or tandem instruments. These very delicate instruments are technically complex. Excellent reviews on their operation and fabrication exist in the literature (see the "Further reading" section).

Examples

To highlight BLS, a selection of examples are discussed. First, the classical application is described: the determination of elastic constants in a bulk transparent material. In this subsection, references to examples are provided where the determination of c_{ij} has been done at high temperatures and high pressures. Then examples of BLS applied to liquids, glasses, opaque materials (surface wave BLS), magnetic materials (magnons) and electronic levels are given.

Determination of elastic constants of a bulk crystal

Fig. 2 shows a Brillouin spectrum obtained from a diamond crystal in the backscattering geometry shown in Fig. 1C. Since the diamond surface was (111) and since the phonons probed in the experiment propagate along the surface normal, the peaks observed in Fig. 2 correspond to phonons along the [111] direction. Along this direction the longitudinal sound velocity is

Fig. 1 Scattering geometries: (A) a bulk-type analysis of excitations inside a transparent material using 90 degrees geometry, (B) a thin transparent layer—this geometry is sensitive to excitations propagating in the plane of the sample, (C) a transparent layer with near-normal incidence—this geometry is sensitive to wave vectors perpendicular to a sample surface, (D) a back-scattering geometry in an opaque material which is sensitive to in-plane, surface wave vectors, and (E) a variant of geometry (D), where $\mathbf{k}'$ is not along the direction of the incident light, is also used for studying surface excitations. For geometries (A) and (C) the material refractive index n is required for data analysis.

$v_L = \sqrt{(c_{11} + 2c_{12} + 4c_{44})/3\rho}$ and the velocity of the (degenerate) transverse phonons is $v_T = \sqrt{(c_{11} - c_{12} + c_{44})/3\rho}$. The peaks in Fig. 2 have therefore been labeled as L and T, respectively.

Since diamond crystals are large enough to be cut and polished with any desired orientation, it is clear that from a combination of measurements in different scattering geometries and/or crystal orientations the whole set of elastic constants can be determined. In Table 1, the c_{ij} of diamond determined by both Brillouin scattering and by ultrasonic techniques are listed. The results of both techniques are in very good agreement but it is interesting to note that while the BLS measurements were performed on crystals of around 1/3 carat, the ultrasonic measurements used a 22 carat diamond.

Fig. 2 Brillouin spectrum from a diamond crystal in the geometry from Fig. 1C. The longitudinal (L) and transverse (T) phonons propagate along the [111] direction.

Table 1 Elastic constants of diamond and boron nitride.

Material and method	c_{11} (GPa)	c_{12} (GPa)	c_{44} (GPa)
Diamond, BLS	1076	125	577
Diamond, ultras	1079	124	578
Boron nitride, BLS	820	190	480

In cases where large, transparent crystals are available, it is clear from Table 1 that BLS has no particular advantage over ultrasonic techniques. However, when only small samples are available the BLS technique becomes the technique of choice. Single crystals of cubic Boron Nitride (BN), for example, cannot be grown as single crystals larger than $\approx 500 \mu\text{m}$. In this case, BLS becomes the technique of choice and yields the c_{ij} also included in Table 1.

The preceding section outlines how BLS can be used to determine c_{ij} . At ambient conditions c_{ij} can often be determined more accurately using ultrasonic techniques. In some cases, however, BLS becomes a much more versatile tool than ultrasonics. Such cases usually involve samples, where transducer bonding is difficult, as it was mentioned above, high pressure and/or high temperature experiments, or cases where chemical reactivity becomes severe. For example, the temperature dependence of the c_{11} and c_{44} elastic constants of $\text{Ba}_{1-x}\text{La}_x\text{F}_{2+x}$ over the range 300–1600 K was determined by P E Ngoepe and J D Comins who found a linear decrease that they attributed to anharmonicity. A case involving high pressures is represented by measurements of liquid and solid argon in a diamond anvil cell up to 70 GPa.

Measurements of spectral features in liquids

BLS can also be used to determine the elastic response of liquids. In contrast to solids, however, where the unshifted peak is dominated by the effects of impurities and surface scattering, in pure liquids the central peak is due to entropy fluctuations. The intensity of the unshifted component is related to that of the shifted BLS peaks via the Landau-Placzek ratio, $C_p/C_v - 1$, where C_p and C_v are the specific heats at constant pressure and volume, respectively. In pure liquids, therefore, BLS can be used to study the intensity and shape of the central peak. Frequency broadening of this peak can be caused by fluctuations in the orientation of anisotropically polarizable molecules or by diffusive processes governed by the equations of hydrodynamics. In liquids, it is also possible to investigate relaxation and damping effects via the phonon lifetime that translates into changes in the shape and line-width of the phonon peaks. The same approach cannot usually be applied to most bulk crystals, because of a very low damping that results in line widths below the experimental resolution. However, in temperature regions where structural phase transitions occur, damping processes influence Brillouin line widths enough so that the changes are detectable, for example, in molten and crystalline alkali halides, during order-disorder transitions in mixed crystals, or during ferroelastic phase transitions in some crystals.

Glasses

BLS has been extensively used to investigate the transition for liquid to solid in materials that do not crystallize: for example, silica, $\text{Rb}_{1-x}(\text{NH}_4)_x/\text{H}_2\text{PO}_4$ (10–300 K), $\text{Rb}_x(\text{NH}_4)_y/\text{H}_2\text{PO}_4$ (20–80 K), and $\text{Ca}(\text{NO}_3)/\text{KNO}_3$ (320–640 K). Across the transition region, the phonons in these materials become highly damped and the resulting line shapes can be interpreted in terms of the underlying mechanism of the glass transition. These types of investigations are also of practical importance, because these materials are often used in fiber optics technology and in optoelectronic devices.

Gases

BLS in gases detects local fluctuations that lead to frequency shifts in the 0.1–1 GHz range. These shifts can also be viewed as a Doppler shift from the motion of individual atoms. In this context, BLS has also been used to investigate how the phonon spectrum evolves as a gas is pressurized to become a fluid. This evolution reflects the hydrodynamic transformation as the thermal mean free path for atomic motion becomes comparable and then shorter than the wavelength at which the medium is being probed by the scattering of visible light. These experiments can also be interpreted in terms of the hydrodynamic equations of motion. Investigations of CO₂ up to 8 atm pressure, and Xe over the range 0.022–0.66 atm are two instances where this phenomenon has been investigated.

Surface acoustic modes in thin layers

Light scattering from acoustic excitations in opaque materials results from a purely surface-induced mechanism, viz. phonon-induced thermal ripples. In these cases, the scattering geometries (d) and (e) in Fig. 1 must be employed. In a semi-infinite medium, the strongest coupling is to Rayleigh waves (reminiscent of waves in the ocean) with some weaker features induced by bulk waves reflecting from the free surface. In thin films and layered structures, however, it is also possible to couple to modes that are localized within the layers or at the interfaces; these modes are generally referred to as Sezawa modes. If the medium is not completely opaque, it is possible to couple to the phonons via both the ripple and elasto-optic mechanisms. In these cases, unusual interference effects are possible.

Fig. 3 shows a BLS spectrum from a Co/Cu superlattice built from 60 bilayers of 1 nm Co/0.8 nm Cu in which the Rayleigh and Sezawa modes are observed. The experiment was carried out using a Sandercock-type tandem 3-pass interferometer. From these results, the effective elastic properties of the superlattice can be extracted.

In cases where the surface layers become much thinner than the wavelength of light, the medium again becomes equivalent to a homogeneous solid. In these cases, Brillouin scattering has been a very efficient and reliable tool for determining the effective elastic constants of the heterogeneous solid. For example, R Danner et al. in the Ni/V superlattice, for different layer thicknesses from the range of 1.85 nm to 63.3 nm, proved that this b.c.c./f.c.c. system reveals softening of elastic parameters. J A Bell with co-workers measured effective elastic constants in the Mo/Ta superlattice (c_{11} , c_{13} , c_{33} , c_{44}) with an elementary spatial bilayer thickness ranging from 0.7 nm to 20 nm.

Observation of bulk and surface spin waves in metallic superlattices

Brillouin scattering can also be used to investigate the magnetic properties of materials via their magnetic excitations—magnons. In this sense, the information it yields is similar to that obtained in Ferromagnetic Resonance (FMR) experiments. However, contrary to FMR that probes the infinite wavelength excitations, Brillouin scattering probes excitations with wavelengths comparable to the wavelength of light. As for phonons, magnons can be subdivided into surface-like and bulk-like excitations. Expressions relating the magnon frequencies to the magnetic properties of the material—magnetization, anisotropies, applied field, and gyromagnetic ratio—can be quite complex and often cannot be rendered in analytical form.

The Brillouin scattering technique has also been used to investigate the nature of magnetic excitations in nonconventional materials. In the case of the Co/Cu superlattice described in the previous paragraph, which is built from alternating magnetic and nonmagnetic materials, bulk-like collective excitations resulting from coupling between spin waves across the nonmagnetic spacer are detected (Fig. 4). Additionally, a surface-like mode propagating on the surface of the sample was also found. The experiment was

Fig. 3 BLS from surface acoustic phonons in the Co/Cu superlattice. Descriptions: R: the Rayleigh surface mode; S: Sezawa or higher-order Rayleigh modes. The measurement was carried out for (s-s) polarizations of the incident and scattered light.

Fig. 4 BLS from spin waves in a multilayered Co/Cu system. Descriptions: D-E: Damon-Eshbach surface mode; BM: (bulk magnon) collective excitations of a bulk-like nature resulting from coupling between spin waves through the nonmagnetic spacer layer. The measurement was carried out for (s-p) polarizations of the incident-scattered light.

Fig. 5 A set of Brillouin spectra measured for different magnetic field intensities in the Co/Cu superlattice. The peaks that appear only on the left side (Stokes signals) result from scattering from a unidirectional surface-like spin wave (D-E mode from Fig. 4).

carried out with a tandem 3-pass spectrometer, with (s-p) polarization of the incident and scattered light, and a constant magnetic field lying in the sample plane. Fig. 5 provides results for different magnetic field intensities, from which the gyromagnetic ratio and saturation magnetization can be determined.

Recent trends and future direction of research

New research directions related to the BLS method are aimed at biomedical applications—on the one hand—and to applications in magnetoelectronics. The progress in the first area is related to the discovery of Virtual Imaged Phased Array (VIPA) by Scarelli and Yun, also developed by Palombo and Fioretto in viscoelastic media. In recent studies of low dimensional magnetic structures it was possible to observe determine interfacial Dzyaloshinskii-Moriya interactions sensed as asymmetry between BLS Stokes and anti-Stokes peaks position. These studies were intensively carried out by Maziewski, Geniusz and others, enabling the study of materials useful for the formation of skyrmions.

Conclusion

Inelastic Brillouin light scattering is a non-destructive measurement technique applicable to the study of the acoustic properties of materials in the hypersonic range. Although the phenomenon itself was discovered relatively long ago, measurements of acoustic

phonons in gases, liquids and solids, including low-dimensional structures, are regularly performed in scientific laboratories. This method, using mainly sophisticated interferometric techniques, is constantly developed and has found applications in the study of magnetoelectronic materials and magnonic excitations in the hypersonic range of frequencies, and importantly, has recently been used in the study of biological and medical samples.

Acknowledgments

I would like to express my gratitude to the people who were my mentors, directly or indirectly, in particular to Marcos Grimsditch (Argonne National Laboratory) for many remote discussions and sharing of research results, to Gernot Güntherodt during my experimental works at RWTH Aachen and to John Sandercock for his support in many moments of my scientific work.

Abstract

Inelastic X-ray scattering (IXS) methodology has matured considerably in the past two decades providing a suite of tools for the study of electronic, dynamic, and magnetic response functions. We provide an introductory overview of IXS techniques most commonly available at modern X-ray light sources. Following a general introduction and the description of the theoretical framework, we discuss IXS from electronic excitations, both resonant and nonresonant, IXS from phonons and collective ion excitations. Conclusions and a short outlook round up this contribution.

Key points

- In an inelastic X-ray scattering experiment, energy and momentum are transferred from an X-ray photon to the sample.
- IXS measures the dynamical structure factor $S(\mathbf{q}, \omega)$, that is, the nonzero frequency correlations in materials.
- Depending on the amount of energy and momentum transferred and whether an experiment is performed at or off resonance, IXS is sensitive to electronic-, magnetic-, and/or lattice-degrees of freedom.
- Modern X-ray light sources have enabled rapid progress in IXS techniques over the last three decades.
- IXS has become truly complementary to inelastic neutron scattering.

Nomenclature

a	Inter particle separation (m)
a_c	Radial extent of core electron wave function (m)
A	Vector potential of the electromagnetic field ($\text{kg m}^2 \text{C}^{-1} \text{s}^{-2}$)
b	Neutron scattering length (1/m)
c	Speed of light (ms^{-1})
E	Energy transfer (eV)
e	Electron charge (C)
$\mathbf{e}$	Photon polarization vector
e_k	Kinetic energy of the photoelectron (eV)

E_c	Core-level binding energy (eV)
E_i	Energy of initial state
E_f	Energy of final state
E_N	Energy of intermediate state
$f(Q)$	Atomic form factor
G	Reciprocal lattice vector (m^{-1})
$\hbar$	Reduced Planck's constant (J s)
J	Exchange integral (eV)
j_n	Bessel function of order n
k	Wave vector (m^{-1})
k_B	Boltzmann constant (J K $^{-1}$)
L	Angular momentum (J s)
M	Atom or ion mass (kg)
m	Electron mass (kg)
n	Electron density (m^{-3})
p	Momentum operator of scattered electrons (kg m s $^{-1}$)
Q	Momentum transfer vector (m^{-1})
Q	Modulus of momentum transfer (m^{-1})
q	Reduced momentum transfer vector (m^{-1})
q	Modulus of reduced momentum transfer (m^{-1})
r	Position operator of the electron (m)
r_0	Classical electron radius (m)
R	Position operator of the ion (m)
S	Total spin moment (μ_B)
$S(Q, \omega)$	Dynamical structure factor (eV $^{-1}$)
T	Temperature (K)
U	Electron-core hole interaction (eV)
v	Sound velocity (ms $^{-1}$)
W	Debye-Waller factor
Z	Number of electrons in an atom
Γ	Lifetime broadening width (eV)
$\varepsilon(Q, \omega)$	Dielectric function
Θ_s	Scattering angle (deg)
ξ	Structural correlation length (m)
ρ	Electron density of states (1/eV)
σ	Cross section (m 2)
σ_n	Phonon eigenvector of mode n
τ	Structural relaxation time (s)
Φ	External potential (V)
χ	Polarization function (C $^{-2}\text{m}^{-2}$)
ω	Angular frequency of radiation (s $^{-1}$)
Ω	Solid angle (rad 2)

Introduction

Inelastic X-ray scattering (IXS) experiments, including both energy and direction (momentum) analysis of the scattered photons, provide an important spectroscopic tool in the study of dynamical electronic-, magnetic-, and lattice degrees of freedom of matter (Hämäläinen and Manninen, 2001; Schülke, 2007; Ament et al., 2011). Two branches of IXS exist: resonant inelastic X-ray scattering (RIXS) and nonresonant inelastic X-ray scattering (NIXS). Within these branches, the different methods can roughly be classified according to the amount of energy and momentum transferred to the sample system and the nature of the excitation.

The different excitations and relative energy scales are schematically illustrated in Fig. 1. IXS from collective ion excitations aims at the study of phonons and phonon-like excitations. It is complementary to inelastic neutron scattering (INS), and has proven to be particularly powerful in cases where INS techniques cannot be applied. Electron dynamics and electronic excitations are studied in various regimes using NIXS. Compton scattering (which will not be further discussed in detail, see contribution by A. Bansil) allows one to determine the electron momentum distribution. IXS from valence and core electrons bears a very close resemblance to electron-energy-loss spectroscopy, X-ray absorption, and photoemission techniques, and gives access to single-particle or collective,

Fig. 1 Schematic X-ray excitation spectrum $S(q, \omega)$ as a function of energy transfer.

electron (plasmon) excitations. Low-energy electronic-, orbital-, and spin-degrees of freedom are probed using resonant IXS. Especially spin degrees of freedom are not easily accessible using nonresonant inelastic scattering. Furthermore, RIXS is element and valence selective.

Despite the fact that most of the IXS techniques were developed several decades ago, they gained their full maturity only after the outstanding properties of electron storage ring-based X-ray sources, in terms of source brilliance and energy tunability, became apparent and modern highly efficient IXS spectrometers with large resolving power became available. IXS experiments are performed over a very large spectral range – from the vacuum-ultraviolet over the soft X-ray range into the hard X-ray regime. Consequently, the associated instrumentation is very diversified, and is based on diffraction gratings for the low energy range, whereas perfect Bragg crystal optics are utilized in the X-ray range. All IXS techniques benefit from the very small beam sizes, in the order of a few tens of micrometers or less, that can presently be obtained at third-generation synchrotron sources (in contrast to milli- to centimeter-sized neutron beam sizes). In the hard X-ray range, these small photon beams even enable IXS at extreme conditions, such as high pressure and high temperature (Rueff and Shukla, 2010).

Theoretical aspects

The basic kinematics of the inelastic scattering process are depicted in Fig. 2. The incident photon of energy $\hbar\omega_1$ and momentum $\hbar\mathbf{k}_1$ are scattered from the sample into a photon of energy $\hbar\omega_2$ and momentum $\hbar\mathbf{k}_2$. The process is therefore characterized by the energy transfer $E = \hbar\omega_1 - \hbar\omega_2$ and the momentum transfer $\hbar\mathbf{Q} = \hbar\mathbf{k}_1 - \hbar\mathbf{k}_2$. Here, the polarization transfer is not considered. In cases where the energy transfer is much smaller than the incident photon energy, $\mathbf{Q}$ is solely controlled by the scattering angle θ_s , and is given by the following expression:

$$Q = 2k_1 \sin(\theta_s/2)$$

The Hamiltonian, describing the electron–photon interaction in the scattering process, is composed, in the weak relativistic limit, of four terms. Neglecting the much weaker magnetic couplings, only two terms have to be retained:

$$H_{\text{int}} = \sum_j \frac{e}{2mc^2} \mathbf{A}_j^2 + \sum_j \frac{e}{mc} \mathbf{A}_j \mathbf{p}_j$$

where $r_0 = e^2/mc^2$ is the classical electron radius, $\mathbf{A}$ is the vector potential of the electromagnetic field, and $\mathbf{p}$ is the momentum operator of the scattering electrons. The sum extends over all the electrons in the system j . Treating the scattering process in the lowest order perturbation theory, representing the vector potential $\mathbf{A}$ in terms of photon creation and annihilation operators, and assuming that both the initial and the final photon states can be represented by plane waves, one obtains, for the double differential cross (DDCS)

Fig. 2 Kinematics of the scattering process.

$$\begin{aligned} \frac{d^2\sigma}{d\Omega d\omega_2} = & r_0^2 \left(\frac{\omega_2}{\omega_1} \right) \sum_F \left| \left\langle F \left| \sum_j e^{i(\mathbf{k}_2 - \mathbf{k}_1) \cdot \mathbf{r}_j} \right| I \right\rangle (\mathbf{e}_1 \cdot \mathbf{e}_2) \right. \\ & \left. - \frac{1}{m} \sum_N \left\{ \frac{\langle F | \mathbf{e}_2 \cdot \sum_j \mathbf{p}_j e^{-i\mathbf{k}_2 \cdot \mathbf{r}_j} | N \rangle \langle N | \mathbf{e}_1 \cdot \sum_j \mathbf{p}_j e^{i\mathbf{k}_1 \cdot \mathbf{r}_j} | I \rangle}{E_N - E_I - \hbar\omega_1 - 0.5i\Gamma_N} + \frac{\langle F | \mathbf{e}_1 \cdot \sum_j \mathbf{p}_j e^{i\mathbf{k}_1 \cdot \mathbf{r}_j} | N \rangle \langle N | \mathbf{e}_2 \cdot \sum_j \mathbf{p}_j e^{-i\mathbf{k}_2 \cdot \mathbf{r}_j} | I \rangle}{E_N - E_I + \hbar\omega_2} \right\} \right|^2 \\ & \times \delta(E_F - E_I - \hbar\omega) \end{aligned} \quad (1)$$

where $\mathbf{e}_1$ and $\mathbf{e}_2$ are the polarization vectors of the incident and scattered photon, respectively, and Γ_N is the lifetime broadening of the intermediate state $|N\rangle$. The δ -function ensures energy conservation. The DDCS is proportional to the number of incident probe particles scattered within an energy range $\Delta E(\Delta\hbar\omega_2)$ and wave vector transfer variation ΔQ into a solid angle $\Delta\Omega$. If the interference terms are neglected, the cross section is composed of three contributions. The first term, derived from the A^2 -term in first-order perturbation, describes nonresonant IXS. The second and the third terms are derived from the $\mathbf{p}\cdot\mathbf{A}$ -term in second-order perturbation. The second term describes an absorption process followed by an emission process, coupled via a resonant intermediate state $|N\rangle$, leading to an increase of the cross section, whenever the energy of the incident photon is close to an absorption edge of the element under study. The third term can be neglected in practical cases.

- (1) *Validity of the adiabatic approximation.* In the adiabatic limit, one can separate the quantum state $|S\rangle$ of a system into the product of an electronic part, $|S\rangle_e$, which depends only parametrically on the nuclear coordinates, and a nuclear part, $|S\rangle_n$: $|S\rangle = |S\rangle_e |S\rangle_n$. This approximation is valid in particular if exchanged energies are small with respect to the excitation energies of electrons in bound core states as is the case for phonon excitations. In this approximation, one neglects the portion of the total electron density contributing to the delocalized bonding states in the valence band region.
- (2) *Limitation to the case for which the electronic part of the total wave function is not changed by the scattering process,* and therefore the difference between the initial state $|I\rangle = |I\rangle_e |I\rangle_n$ and the final state $|F\rangle = |F\rangle_e |F\rangle_n$ is due only to excitations associated with atomic density fluctuations.

More in-depth introductions to the theory of resonant and NIXS can be found in, for example, [Sinha \(2001\)](#), [Schülke \(2007\)](#), [De Groot and Kotani \(2008\)](#), and [Haverkort \(2010\)](#).

IXS from electronic excitations

In the following, the various IXS processes, which arise from electronic excitations (with the exception of Compton scattering) are discussed. These can be roughly divided into two main fields according to the corresponding piece of the DDCS: (1) nonresonant IXS and (2) resonant IXS. In contrast to spectroscopies utilizing electron detection, IXS experiments are bulk sensitive and, if performed in the hard X-ray regime, allow one to study systems under extreme conditions such as very high temperatures and pressures.

NIXS from electrons

The cross section for nonresonant IXS is derived from the A^2 term of the interaction Hamiltonian and constitutes the first term in the expression of the DDCS. The DDCS can be factorized into two parts, the first describes the coupling of the scattering probe to the system, and the second contains the properties of the system in the absence of the perturbing probe:

$$\frac{d^2\sigma}{d\Omega d\omega_2} = r_0^2 (\mathbf{e}_1 \cdot \mathbf{e}_2)^2 \left(\frac{\omega_1}{\omega_2} \right) S(\mathbf{Q}, \omega) = \left(\frac{d\sigma}{d\Omega} \right)_{\text{Th}} S(\mathbf{Q}, \omega)$$

where $(d\sigma/d\Omega)_{\text{Th}}$ is the Thomson scattering cross section. The dynamical structure factor $S(\mathbf{Q}, \omega)$ contains the information about electronic excitations via the imaginary part of the dielectric response function $1/\varepsilon(\mathbf{Q}, \omega)$:

$$\frac{1}{\varepsilon(\mathbf{Q}, \omega)} = 1 + \frac{4\pi e^2}{Q^2} \chi(\mathbf{Q}, \omega),$$

where $\chi(\mathbf{Q}, \omega)$ connects the Fourier-transformed induced charge $n_{\text{ind}}(\mathbf{Q}, \omega)$ with the Fourier transform of the external potential $\Phi_{\text{ext}}(\mathbf{Q}, \omega)$:

$$n_{\text{ind}}(\mathbf{Q}, \omega) = -e\chi(\mathbf{Q}, \omega)\Phi_{\text{ext}}(\mathbf{Q}, \omega)$$

The basic ingredient of the polarization function is the so-called Lindhard polarization function, which describes the polarization of a homogeneous electron system by taking into account all single-particle excitation processes (particle-hole excitations) mediated by the momentum transfer, assuming that they are allowed by Pauli's principle, but neglecting the interaction of the particle and the hole with the surrounding electron fluid as well as any interaction between the particle and the hole left behind. A first step of approximating the Lindhard polarization function is the so-called random phase approximation (RPA) where, in addition to the external potential, the potential due to the induced polarization also acts on the system.

Fig. 3 Upper panel: real and imaginary part of the RPA dielectric function $\epsilon_{\text{RPA}}(Q, \omega)$ for $Q < Q_c$, $Q = Q_c$, and $Q > Q_c$. Lower panel: corresponding imaginary part of $-\epsilon_{\text{RPA}}^{-1}(Q, \omega)$. (Adapted from M. Krisch, F. Sette, *Scattering, Inelastic: X-Ray (Methods and Applications)*, Editor(s): Franco Bassani, Gerald L. Liedl, Peter Wyder, *Encyclopedia of Condensed Matter Physics*, Elsevier, 2005, pp. 220–226, with permission)

IXS from valence electrons

Fig. 3 shows three characteristic $S(\mathbf{Q}, \omega)$ spectra along with the real and imaginary parts of the dielectric function $\epsilon(\mathbf{Q}, \omega)$. The evolution of the spectra can be understood by inspection of $\epsilon(\mathbf{Q}, \omega)$ and $\text{Im}[\epsilon(\mathbf{Q}, \omega)^{-1}]$ for three different regimes of the momentum transfer Q . Within the RPA formalism, a sharp structure in the $S(\mathbf{Q}, \omega)$ appears at a frequency $\omega = \omega_p$, the plasma frequency of the system, when $\text{Re}[\epsilon(\mathbf{Q}, \omega)]$ has a zero passage and simultaneously $\text{Im}[\epsilon(\mathbf{Q}, \omega)]$ is close to zero. This behavior persists up to the so-called critical momentum transfer Q_c , for which the zero passage of $\text{Re}[\epsilon(\mathbf{Q}, \omega)]$ coincides with the high-energy cutoff of $\text{Im}[\epsilon(\mathbf{Q}, \omega)]$. In the above regime of $Q < Q_c$, the plasmon dispersion can be determined. For $Q > Q_c$, the plasmons can decay into particle–hole excitations, and a much larger spectral range yields a significant contribution to the $S(\mathbf{Q}, \omega)$. A comparison of the experimental spectra with relevant calculations gives an insight into electron correlation and band-structure effects. Moreover, IXS allows one to determine the bandgap of semiconductors or insulators, and—in the case of an indirect gap—its relative momentum. Furthermore, IXS spectra recorded in the particle–hole excitations regime provide information about the combined electron density of states. Finally, one gains access to the off-diagonal response of the dynamical structure factor by performing the IXS experiment in the presence of a standing-wave field, generated by the coherent superposition of an incident and diffracted wave vector when the sample is positioned in Bragg reflection conditions (Schülke and Kaprolat, 1991).

IXS from core electrons (X-ray Raman scattering)

One often refers to NIXS from core electrons or X-ray Raman scattering spectroscopy if the final state $|F\rangle$ of the electron system is characterized by a hole in a core level and an electron in a continuum state above the Fermi level. Within the RPA, the dynamical structure factor takes the following form:

$$S(\mathbf{Q}, \omega) = \left(\frac{\hbar Q^2}{4\pi e^2 n} \right) \sum_{k', v'} |\langle \mathbf{k}' v' | \exp(i\mathbf{Q} \cdot \mathbf{r}) | c \rangle|^2 \times \delta(\hbar\omega + E_c - E(\mathbf{k}', v)),$$

where $|c\rangle$ is a core state with energy E_c and $E(\mathbf{k}', v)$ is the energy of a one-electron Bloch state with reduced wave vector $\mathbf{k}'$ and band index v . The characteristics of the electronic transition are controlled by the transition operator $\exp(i\mathbf{Q} \cdot \mathbf{r})$.

XRS from core electrons of low Z materials is analogous to soft X-ray absorption spectroscopy (XAS) as long as the momentum transfer Q is small compared with the radial extent a_c of the wave function of the core electron involved in the inelastic scattering process (Mizuno and Ohmura, 1967). A Taylor expansion of the transition operator yields

$$\exp(i\mathbf{Q} \cdot \mathbf{r}) \approx 1 + i\mathbf{Q} \cdot \mathbf{r} - \frac{1}{2}(\mathbf{Q} \cdot \mathbf{r})^2 + \mathcal{O}((\mathbf{Q} \cdot \mathbf{r})^3),$$

where the leading term $i\mathbf{Q} \cdot \mathbf{r}$ is equivalent to the dipole transition operator for X-ray absorption if the momentum transfer $\mathbf{Q}$ in XRS takes the role of the photon polarization vector $\mathbf{e}$ in XAS. At finite momentum transfer $|\mathbf{Q}| \gg a_c$, the Taylor expansion breaks down and, instead, a multipole expansion of the transition operator in terms of spherical harmonics yields:

$$\exp(i\mathbf{Q} \cdot \mathbf{r}) = \sum_{k=0}^{\infty} \sum_{m=-k}^k i^k (2k+1) j_k(Qr) \times C_{km}^*(\theta_Q, \phi_Q) \times C_{km}(\theta_r, \phi_r),$$

where j_k are k th-order spherical Bessel functions containing the dependence of $S(\mathbf{Q}, \omega)$ on the modulus of the exchanged momentum Q and $C_{km} = \sqrt{4\pi/(2k+1)} Y_{km}$ are renormalized spherical harmonics, which describe the $\mathbf{Q}$ -directional dependence of the transition operator. Three-dimensional representations of the angular part of the transition operators by means of a coherent sum over all terms $\sum_m C_{km}(\theta_r, \phi_r)$ are shown for monopole ($k=0$), dipole ($k=1$), quadrupole ($k=2$), octupole ($k=3$), hexadecapole ($k=4$), and triakontadipole ($k=5$) operators in Fig. 4.

Fig. 4 Three-dimensional representations of the angular part of the transition operators: monopole ($k = 0$), dipole ($k = 1$), quadrupole ($k = 2$), octupole ($k = 3$), hexadecapole ($k = 4$), and triakontadipole ($k = 5$) operators.

The sensitivity of XRS to systems with higher than twofold rotational symmetry as opposed to XAS (dipole transitions) is immediately obvious based on the complex shape of these operators and is taken advantage of for studying linear dichroism in cubic systems (Gordon et al., 2009). If the initial state has spherical symmetry (s -orbitals), the angular dependence of XRS edges directly reflects the shape and orientation of the final state (e.g., d -orbitals in transition metal oxides and/or f -orbitals in the lanthanides) (Yavaş et al., 2019).

As a further consequence of the presence of these higher order multipole terms at large momentum transfer $\hbar Q$, the electric dipole selection rule, defining the final state symmetry, which can be reached in an absorption process, is relaxed and XRS can be used to extract the local core-excited electronic density of states $\rho(\hbar\omega)_L$ via

$$S(Q, \omega) \propto \sum_L M(\hbar\omega)_L \rho(\hbar\omega)_L,$$

with the matrix elements $M(\hbar\omega)_L$ for the given angular momentum channel $L = (l, m)$ (Soininen et al., 2006).

A great advantage of XRS over conventional XAS is that while in XAS the incident photon energy has to be tuned to the absorption edge energy under consideration, in XRS this role is taken by the energy transfer, thus leaving a certain freedom in the choice of the incident photon energy. This is schematically illustrated in Fig. 5. XRS therefore allows one to perform soft X-ray absorption studies in the hard X-ray regime, with the advantage of probing truly bulk properties and study systems which are not compatible with an ultrahigh vacuum environment, necessary in the soft X-ray regime. This is especially true for samples contained in complex *in situ* environments, such as diamond anvil cells for high pressure studies. The nonresonant character also renders the core excitation spectra practically free of artifacts such as self- or over-absorption and easier to treat theoretically as the transitions are describable by one-electron operators.

Resonant inelastic X-ray scattering

The cross section for resonant inelastic X-ray scattering (RIXS) is derived from the $\mathbf{p} \cdot \mathbf{A}$ -term in the interaction Hamiltonian, and constitutes the second term of the DDCS. It is a second-order optical process, in which a core electron is excited by an incident X-ray photon of energy $\hbar\omega_1$ into empty states above the Fermi level. This excited state then decays, and the deep core hole is filled by an

Fig. 5 Schematic representation of the X-ray absorption (left) and X-ray Raman scattering (right) process. E_c denotes the binding energy of a core level, and e_k is the kinetic energy of the photoelectron.

Fig. 6 Schematic representation of the RIXS process for direct RIXS (A) and indirect RIXS (B).

electron from a shallower core level or the valence band under emission of a photon of energy $\hbar\omega_2$ (see Fig. 6). In the most common case, both the excitation and de-excitation steps involve electric dipolar transitions. If the intermediate core-excited states are closely located in energy, interference between the absorption and emission process is possible (Revelli et al., 2019). The success of RIXS rests on the fact that elementary excitations, such as plasmons and charge-transfer excitations, excitons, and intra-orbital excitations (e.g., *dd* excitations), collective magnetic excitations, such as magnons and bi-magnons, as well as phonons down to the meV energy scale can be probed with a cross section that is enhanced due to the resonant nature of the RIXS process. Also, the electron–phonon coupling can be measured since it is related to the intensity of the phonons as measured by RIXS (Rossi et al., 2019). Depending on how energy and momentum are transferred during the lifetime of the intermediate state, two different RIXS mechanisms are usually differentiated: direct RIXS and indirect RIXS. In direct RIXS (Fig. 6A), a core electron is resonantly excited into an empty state above the Fermi level and a different electron from an occupied valence level fills the core hole leaving the system in a final state with an electron–hole excitation of energy $\hbar\omega = \hbar\omega_1 - \hbar\omega_2$ and momentum $\hbar Q = \hbar Q_2 - \hbar Q_1$. In indirect RIXS (Fig. 6B), on the other hand, the excited and decaying electrons are identical and the excitation is created via shake-up process due to the strong electron–core hole interaction (U) in the intermediate state. The cross section for indirect RIXS is, therefore, considerably lower than that for direct RIXS.

Dynamics in the time domain can be assessed if the intermediate state undergoes a transition (emission or absorption of a phonon) in the time interval between the excitation and the emission step (Björneholm et al., 1997). The rate for this transition can then be directly compared to the core hole decay rate, and information about the time development in the range of the core hole lifetime can be obtained. Well above the absorption threshold, the IXS process can be regarded as a decoupled two-step process, and is commonly dubbed X-ray fluorescence.

In general, a simple one-electron picture is not sufficient to account for all the observed phenomena. Especially for open shell systems, such as transition metals or rare earths, a many-body description has to be invoked. Despite these complexities, RIXS is a very powerful spectroscopic tool, thanks to its high degree of selectivity. It is element and angular momentum selective (via its resonant intermediate state and the transition selection rules, respectively). Site selectivity with respect to identical atomic species in different chemical environments can be obtained by choosing an excitation energy so that a core electron is promoted to an unoccupied state which has a strong localization on that particular site. Detecting the scattered X-rays with angular selectivity adds further information: in solids band-structure information can be obtained, whereas for molecules, the symmetry of molecular states

can be studied. Furthermore, exploiting the unique polarization properties of synchrotron-based X-ray sources, linear and circular dichroism phenomena can be studied. As in the case of nonresonant IXS, the various applications can be roughly classified according to the transferred energy.

RIXS from valence electrons

These experiments aim at detecting low-lying electronic excitations such as interband, *d-d*, and charge-transfer excitations. To perform these experiments at resonance with a characteristic absorption edge bears several advantages: (1) the resonant enhancement of the cross section of typically two orders of magnitude allows one to study essentially all compounds of interest while nonresonant IXS is practically limited to low *Z* materials; (2) the presence of (an) intermediate state(s) and eventual interference effects between them make the RIXS process highly selective in terms of angular momentum selection rules and geometrical considerations when the experiment is performed on single crystals. For example, the shape of resonantly excited valence fluorescence spectra from single crystals depends strongly on the energy of the incident photon and the momentum transfer **Q** (both direction and size), which is a direct consequence of momentum conservation, stating that **Q** must be equal to the vector difference $\mathbf{k}_e - \mathbf{k}_h$ between the Bloch vectors of the excited electron and those of the hole left behind, modulo a reciprocal lattice vector **G**. This Bloch **k**-selective RIXS allows, in principle, one to obtain band-structure information although attention has to be paid to the relaxation processes in the intermediate state (Ma et al., 1992; Enkisch et al., 1999).

The momentum transfer dependence of RIXS can further be used to probe elementary excitations, such as excitons and orbitons, and collective excitations, such as plasmons, across the Brillouin zone. Even for transition metal L-edges, lying in the soft X-ray regime, large portions of reciprocal space are often accessible. Access to spin-flip excitations and, therefore, to collective spin excitations such as magnons is possible if the intermediate state is split by spin-orbit interaction and the dispersion of magnetic excitations can be probed (Braicovich et al., 2010). Recent advances in experimental setups and theory have helped to establish RIXS as a complementary technique to inelastic neutron scattering with the advantage of being able to measure small samples and samples containing strong neutron absorbers such as iridium.

RIXS from core electrons

Since the final state of the RIXS process is characterized by a hole in a shallow core level (or the valence band), spectral features narrower than the intermediate state lifetime width can be observed (Hämäläinen et al., 1991; Krisch et al., 1995). The ultimate resolution is limited by the final-state lifetime width. If these final state RIXS features are associated with different excitation channels (located at different energies in the intermediate state), they will resonate at different incident photon energies. RIXS, therefore, can reveal different excitation channels that are completely obscured in the corresponding X-ray absorption spectrum due to the large core hole lifetime width. This allows, for example, one to determine the energy position and the relative strength of weak quadrupolar (*2p* – *4f*) transitions in rare-earth compounds. Absorption spectroscopy-like experiments utilizing this mechanism are often coined high-energy resolution fluorescence detected (HERFD) XAS or simply resonant X-ray emission spectroscopy (RXES).

Spin selective RIXS – > nonresonant XES

The shape of X-ray fluorescence spectra of elements, which contain an open electronic shell (e.g., transition metals or rare earths), shows characteristic shoulders or satellites which reflect the energies of the different electronic configurations of the excited atom. Besides the Coulomb interactions between the electrons occupying different orbital configurations, there are some interactions that have a magnetic origin, in particular in cases where the excited atom has valence electrons with unpaired spin giving rise to a magnetic moment. These exchange interactions between the magnetic electrons of the valence shell and the core electrons in the orbital where the photon emission process has left a core hole lead to features in the emission spectrum of dominant spin character. The energy separation is related to the strength of these interactions, which are largest when the hole is in an orbital with the same principal quantum number *n* of the magnetic electrons. In a simple picture, the X-ray emission is separated into high- and low-spin states whose energy separation is proportional to the exchange integral *J* and $(2S + 1)$, where *S* is the total spin moment of the magnetic shell, and whose intensity ratio is given by $S/(S + 1)$. Changes in the magnetic state (induced, e.g., by pressure, temperature, or doping) can therefore be witnessed by changes in the X-ray emission lineshape. By its nature, this method does not need a long-range magnetic order, and it is sensitive to the local (atomic) magnetic spin moment of a specific valence orbital. As a consequence, however, the method cannot discriminate between ferro-, antiferro-, ferri-, and paramagnetism.

Dichroism effects in RIXS – > RIXS-mcd

Resonant IXS and fluorescence spectral shapes are sensitive to both the polarization of incident and scattered photons. In ferromagnetically aligned samples, the emission spectra therefore display dichroic effects, in close analogy to X-ray absorption spectroscopy utilizing circular or linear polarized X-rays. RIXS from valence electrons, excited with circular polarized X-rays, provides information on the occupied spin density (Krisch et al., 1996; Sikora et al., 2010), whereas RIXS from core electrons allows one to reveal the magnetic character of the predominant features composing the emission line. The X-ray emission linear magnetic dichroism effect represents the angular dependence of the X-ray emission cross section with respect to the magnetization axis. For a given configuration, the sizes of these dichroic effects are proportional to the magnetic moment of the involved magnetic shell (Thole et al., 1992).

IXS from phonons

The study of atomic dynamics in condensed matter systems at momentum transfers Q and energies characteristic of collective motions is traditionally the domain of neutron scattering spectroscopy. There are, however, situations where the use of photons has important advantages over neutrons (Burkel, 2000; Baron, 2016, 2019). The most significant is that there are no kinematic limitations: for IXS, any energy transfer can be reached for a given momentum transfer, whereas for INS, due to the neutron mass and typical neutron energies, the small- Q range is not accessible. This is depicted in Fig. 7 for different scattering angles Θ_S .

In its most general form, the DDCS can be written as

$$\frac{d^2\sigma}{d\Omega d\omega_2} = r_0^2 (\mathbf{e}_1 \cdot \mathbf{e}_2)^2 \left(\frac{\omega_2}{\omega_1} \right) \sum_{I_n, F_n} P_{I_n} \times \left| \langle F_n | \sum_j f_j(\mathbf{Q}) e^{i\mathbf{Q} \cdot \mathbf{R}_j} | I_n \rangle \right|^2 \times \delta(\hbar\omega + \hbar\omega_2 - \hbar\omega_1)$$

where $|I_n\rangle$ ($|F_n\rangle$) are the initial (final) nuclear states, P_{I_n} represents the thermal population of the initial states, and $f_j(\mathbf{Q})$ is the atomic form factor of the j th particle whose center-of-mass position is at $\mathbf{R}_j$. With respect to the INS cross section, the following aspects are noteworthy.

1. X-rays couple to the electrons of the system with a cross section proportional to the square of the classical electron radius, $r_0 = 2.82 \times 10^{-15}$ m, that is, with a strength comparable to the neutron-nucleus scattering cross section b^2 .
2. The IXS cross section is proportional to $f_i(\mathbf{Q})$. In the limit $Q \rightarrow 0$, the form factor is equal to the number of electrons in the scattering atom, Z ; for increasing values of Q , the form factor decays with decay constants of the order of the inverse of the atomic wave function dimensions of the electrons in the atom.
3. For elements with $Z > 4$ and typical X-ray energies of 10–30 keV, photoelectric absorption is the main attenuation process. Far away from any absorption resonances, it is roughly proportional to Z^4 , leading therefore to a reduction of the cross section for heavier elements.
4. The cross section for X-rays is highly coherent; therefore, only static or quasistatic structural and/or chemical disorder contributions have to be considered. Finally, it is noted that the instrument resolution function for IXS is independent of the energy and momentum transfer.

For the particular case of IXS from phonons at a given temperature T , the dynamical structure factor for one-phonon contribution becomes

$$S(\mathbf{Q}, \omega) \propto \sum_n F_n(\mathbf{Q}, \omega) G_n(\mathbf{Q})$$

$$F_n(\mathbf{Q}, \omega) = [\delta(\omega - \omega_n(\mathbf{q})) - \delta(\omega + \omega_n(\mathbf{q}))] \times \left[\omega_n(\mathbf{q}) (1 - \exp(-\frac{\hbar\omega}{k_B T})) \right]^{-1}$$

$$G_n(\mathbf{Q}) = \left| \sum_j \mathbf{Q} \cdot \boldsymbol{\sigma}_n^j(\mathbf{q}) \frac{f_j(\mathbf{Q})}{\sqrt{M_j}} \exp[-W_j(\mathbf{Q}) + i\mathbf{Q} \cdot \mathbf{R}_j] \right|^2$$

where ω_n is the phonon eigenfrequency for mode n , and $\boldsymbol{\sigma}_n$ is the eigenvector for mode n in periodic notations. Here, $\mathbf{q} = \mathbf{Q} - \mathbf{G}$ is the reduced momentum transfer with the reciprocal lattice vector $\mathbf{G}$, and W_j is the Debye–Waller factor.

Fig. 7 Accessible energy–momentum transfer regions for inelastic neutron scattering for different scattering angles Θ_S , reported normalized to the incident neutron energy $\hbar\omega_1$ and incident neutron momentum $\hbar k_1$.

If the energy resolution of the experiment is much larger than the energy scale of the phonons, that is, if no energy analysis is applied, the formalism of so-called thermal diffuse scattering reduces to

$$S(\mathbf{Q}) \propto \sum_j \frac{1}{\omega_n(\mathbf{q})} \coth \left[\frac{\hbar \omega_n(\mathbf{q})}{2k_B T} \right] G_n(\mathbf{Q}).$$

While the energy-related information is not directly recoverable via the measurement of thermal diffuse scattering, it can provide valuable indications about the regions of interest in reciprocal space to be explored by energy-resolved IXS. In simple cases, the phonon dispersion can be derived directly from the q -dependence of the thermal diffuse scattering intensity (Xu and Chiang, 2005).

Preliminary calculations of lattice dynamics, even semi-quantitative, are highly beneficial for the experiment planning, as intensity and contrast for a given phonon can be optimized with the knowledge of eigenfrequencies and eigenvectors (thus selection rules).

Phonons in crystalline materials

The capability of providing micrometer-sized X-ray beams opens up the possibility of studying systems available only in small quantities down to a few 10^{-6} mm^3 . These comprise novel or advanced materials such as superconductors for which sufficient crystalline quality and homogeneous doping can only be obtained for tiny crystals, by far too small to be studied by INS. Moreover, materials can be studied under very high pressures ($> 100 \text{ GPa}$) using diamond anvil cells, thus allowing important insights into the dynamics close to structural phase transitions and the pressure evolution of elastic properties. IXS from phonons in single crystalline materials provides the same information as coherent INS, and all aspects of lattice dynamics in terms of symmetry considerations, phonon eigenvectors, and selection rules are identical. One exception, however, concerns the relative intensity of the phonons in a multi-species system (with j different atom species in the unit cell), which can be very different due to the different weight of the atomic form factor $f_j(\mathbf{Q})$ with respect to the neutron scattering length b_j .

For polycrystalline materials, only the modulus of Q is well defined, and in general the $S(Q, \omega)$ spectrum will contain contributions from all the phonon branches. The density-of-states limit is reached, if a fine sampling of a sufficiently large Q -space is performed. On the other hand, if Q is confined within the first Brillouin zone, $Q = q$, only phonon modes which have a longitudinal symmetry component are excited, allowing the determination of an orientation-averaged acoustic phonon dispersion.

High-frequency dynamics in liquids and glasses

The absence of kinematic limitations for IXS has allowed one to access a previously unexploited region in $Q - \omega$ space, the so-called mesoscopic region, in which the momentum transfer $\hbar Q$ approaches the inverse of the interparticle separation a (Sette et al., 1998). This Q -range is particularly important because here the collective dynamics undergoes a transition from a hydrodynamic to a microscopic single-particle behavior. Numerous IXS studies in glasses have identified—despite qualitative differences—several common features in the high-frequency dynamics.

1. Propagating acoustic-like excitations exist up to a maximum Q -value Q_m ($Q_m a \approx 1-3$), depending on the fragility of the system.
2. The excitations are well defined and display a linear dispersion $\hbar \omega(Q)$. An extrapolation toward the $Q \rightarrow 0$ limit yields the macroscopic sound velocity.
3. The width $\Gamma(Q)$ of the inelastic peaks follows a power law, $\Gamma = DQ^\alpha$ with $\alpha = 2$ within the current experimental accuracy.
4. The value of D does not depend significantly on temperature, indicating that this broadening in the high-frequency region does not have a dynamic origin, but is instead due to static disorder.

For liquids, the dynamical structure factor is strongly affected, if the probed distances ($l = 2\pi/Q$) are comparable to those that characterize structural correlations among particles (over typical correlation lengths ξ), and times ($t = 1/\omega$) comparable to the lifetime t of these correlations. In this case, one observes a positive sound dispersion $v(Q)$ from its low-frequency ($\omega = 2\pi\nu \ll 1/\tau$) adiabatic value $v(0)$ to the high-frequency ($\omega \gg 1/\tau$) elastic value v_∞ . A quantitative analysis of the $S(Q, \omega)$ can be performed within the framework of a generalized Langevin equation formalism using the memory function approach. This allows the reliable extraction of ν_∞ , relaxation times, and relaxation strengths.

Deep IXS

Quantitative information on the atomic momentum distribution can be obtained at sufficiently large momentum transfers, where the core electrons of the system under study recoil almost freely with an effective mass equal to the atomic mass (Monaco et al., 2002). These conditions are met, if the electron dynamics is instantaneous compared to the atomic one and if the atoms have an appropriate quantity of electronic charge on a length scale smaller than $1/Q$. Deep IXS provides a complementary technique to deep INS, and is particularly valuable for polyatomic or polyisotopic systems, for which the relative contrast between the different atomic/isotopic species in the sample is different for INS and IXS.

Conclusion

IXS provides a range of experimental techniques for the study of dynamic electronic-, magnetic-, and lattice degrees of freedom. The advent of synchrotron X-ray sources provided a fertile ground for the exploration of a wide range of IXS techniques that were then definitely established as powerful spectroscopic tools at third-generation synchrotron X-ray sources, truly complementary to inelastic neutron scattering techniques. The advent of fourth-generation synchrotron X-ray sources, close to the diffraction limit, will nurture further developments both experimentally and theoretically. In particular studies in operando and studies of minute amounts of samples at extreme conditions of pressure and temperature, electric and magnetic fields and set-ups allowing for time-resolution will allow exploring so far uncharted territory with broad applications in fields such as materials science, chemistry, catalysis, and earth and planetary sciences. In parallel, IXS at free-electron lasers is expected to offer additional opportunities with particular emphasis in the study of time-resolved phenomena.

Abstract

Nuclear resonant scattering (NRS) is a set of experimental techniques that use synchrotron radiation (SR) to excite well-defined resonances in atomic nuclei. Studies using NRS require isotopes with large nuclear resonant cross sections and transition energies matching high intensity SR sources. NRS methods typically use timing techniques which makes observation of NRS from isotopes with very short lifetimes technically difficult and resonant energy widths of the order of 10 neV are favorable. Nuclear resonant inelastic x-ray scattering (NRIXS) for the study of lattice dynamics and synchrotron Mossbauer spectroscopy (SMS) for the study of hyperfine interactions have become of practical importance during the past decade at highly brilliant SR facilities.

SMS is elastic forward scattering without nuclear recoil, i.e., without lattice excitation, and provides information about the electronic environment of the resonant nuclei analogous to conventional Mossbauer spectroscopy. The use of very collimated synchrotron radiation permits focusing to micrometer levels and easy manipulation of x-ray polarization.

NRIXS is used for the study of lattice vibrations and provides us with a spectrum of the phonons experienced by the resonant isotope. Most importantly one determines the phonon density of states (PDOS.) In contrast to other experimental techniques, NRIXS gives direct access to the partial and projected PDOS of the resonant isotope only. Complete isotope selectivity is truly unique in the area of lattice dynamics research.

Both techniques have been applied very successfully in studies at Mbar-pressure, biophysics research, and nanostructures. For applied studies, highly flexible and tested evaluation softwares, CONUSS for SMS and PHOENIX for NRIXS, are available as open source free of charge at <https://www.nrixs.com>.

Introduction

Nuclear resonant scattering (NRS) is a set of experimental techniques that use synchrotron radiation (SR) and well-defined resonances in atomic nuclei (Gerdau et al., 1985). Dynamics of the neutrons and protons cause a spectrum of these resonances for every nucleus except hydrogen. A nucleus can be created in an excited state by radioactive decay of a parent nucleus, or it can be

[☆]Change History: July 2022. W Sturhahn prepared the article and all updates/additions. Introduction, references, and outlook were updated from previous Encyclopedia article. Relevant website and key points were added

Fig. 1 Resonant excitation of a nucleus. The energy width of the excited state is typically 12 orders of magnitude smaller than the energy of the photon. Nuclei show the most narrow resonances in the x-ray regime.

brought into an excited state by collision with energetic particles (electrons, protons, neutrons, etc.) or the absorption of a photon. The latter process, a resonant excitation, becomes important if the energy of the photon is very close to the energy difference between the nuclear ground state and a nuclear excited state (see Fig. 1). Studies using NRS require isotopes with large nuclear resonant cross sections and transition energies that can be matched with high intensity by SR sources. NRS methods use timing techniques, and the observation of NRs from isotopes with very short lifetimes is technically difficult. Therefore, energy widths of the excited state of the order of 10^{-8} eV are favorable. Large values potentially result in higher counting rates in scattering experiments but also lead to shorter natural life times.

Spectroscopic techniques with nuclear resonances are based on either the use of radioactive sources or parent nuclei, e.g., Mössbauer spectroscopy and time-perturbed angular correlation (TPAC), or the direct excitation with photons, e.g., nuclear magnetic resonance (NMR) or the SR-based NRS described here. Nuclear resonant inelastic x-ray scattering (NRIXS) for the study of lattice dynamics and synchrotron Mössbauer spectroscopy (SMS) for the study of hyperfine interactions have become of practical importance during the past decade at highly brilliant SR facilities (Gerdau and de Waard, 1999/2000; Sturhahn, 2004; Langouche and Yoshida, 2021). SMS includes scattering processes that occur without recoil, i.e., without participation of lattice vibrations, and provides information about the electronic environment of the resonant nuclei analogous to conventional Mössbauer spectroscopy. The use of very collimated synchrotron radiation permits focusing to micrometer levels and easy manipulation of x-ray polarization. SMS has been applied very successfully to problems in high-pressure and biophysics research. In the study of magnetism, the strategic use of the isotopes ^{57}Fe (resonant) and ^{56}Fe (nonresonant) opened unique possibilities for analysis of thin films and nanostructures.

NRIXS is used for the study of lattice vibrations and provides us with a spectrum of the phonons experienced by the resonant isotope. Most importantly one determines the phonon density of states (PDOS). In contrast to other experimental techniques, NRIXS gives direct access to the partial and projected PDOS of the resonant isotope only (Sturhahn et al., 1995). This complete isotope selectivity is truly unique in the area of lattice dynamics research. For example, materials surrounding the sample that do not contain resonant nuclei do not produce background, and this feature permitted high-pressure experiments in the Mbar regime that were impossible before (Sturhahn and Jackson, 2007). Many proteins contain only a few iron atoms at their biologically active sites; NRIXS studies using ^{57}Fe were conducted on several model compounds for such proteins, as well as on the proteins themselves. Among the thousands of atoms, NRIXS selects only the iron vibrations and thus permits detailed studies of protein dynamics related to these active sites. The same reasoning applies to studies of thin films and buried interfaces. Also for nanoparticles and disordered alloys, the NRIXS method has been applied very successfully. In those cases, as well as for amorphous materials, phonon dispersions are difficult or impossible to measure, but the PDOS still gives valuable information.

For both techniques, highly flexible and tested evaluation software, CONUSS for SMS and PHOENIX for NRIXS, are available as open source free of charge at <https://www.nrixs.com>.

Properties of nuclear resonances

X-ray scattering is usually treated solely with the electronic charge and spin. A justification is provided by classical electrodynamics in terms of the Thomson-scattering cross section, which is a factor of $(Z m/M)^2 \approx 10^{-7}$ smaller for the nucleus than for the electron shell. Here m , M are the masses of electron and nucleus, respectively, and Z is the atomic number. Based on this, it seems appropriate to ignore scattering contributions from the nucleus. However, the above argument fails if the time scale of internal nuclear dynamics matches the energy of the x-ray photon, i.e., the nucleus experiences a resonant excitation. Then the nuclear resonant cross section is calculated as

$$\sigma_N = \frac{\lambda^2}{2\pi} \frac{1}{1 + \alpha} \frac{2I' + 1}{2I + 1}, \quad (1)$$

where λ is the wavelength of the resonant x rays, α is the internal conversion coefficient, and I , I' are the spins of nuclear ground and excited state. Values of α for relevant nuclear transitions range from 1 to 1000. The nuclear resonant cross section can become very large, e.g., the 14.4 keV nuclear transition of ^{57}Fe gives (with $\lambda = 86$ pm, $\alpha = 8.6$, $I = 1/2$, $I' = 3/2$) a value of $\sigma_N = 2.56$ Mbarn and a ratio of $\sigma_N/\sigma_{pe} \approx 450$, where σ_{pe} is the photoelectric cross section. Fig. 2 displays nuclear resonant cross sections and nuclear level widths for isotopes with resonances below 150 keV. Higher transition energies are less favorable because the intensity of SR

Fig. 2 Level widths of nuclear resonances below 150 keV. The size of the symbols is proportional to the nuclear resonant cross section. Prominent isotopes that have been used in NRS experiments are identified.

Fig. 3 Scattered intensity versus time. At zero time, a SR pulse excites a sample containing a nuclear resonant isotope. Electronic scattering is prompt whereas the response of the resonant nuclei is delayed. Time discrimination is the key to distinguishing nuclear and electronic scattering.

sources decreases, and x-ray optics, as well as detectors, become less efficient. Even though the nuclear resonant cross section is very large, the extraordinarily narrow energy width of these resonances leads to small energy-integrated cross section. For example, the best energy resolutions of x-ray optics are of the order $\delta E \approx 100 \mu\text{eV}$, and a resonant enhancement over a neV scale would remain unresolved and unnoticed because $\sigma_N \Gamma \ll \sigma_{pe} \delta E$. Therefore NRS experiments require special observation techniques.

A sample containing resonant nuclei responds to a SR pulse on a time scale defined by the lifetime of the nuclear state τ . The value of τ is inversely related to the nuclear level width via $\tau \Gamma = \hbar$. Whereas values for τ are in the ns- μs range, the duration of a SR pulse is typically less than 100 ps. All electronic scattering of x rays occurs typically on the time scale of femtoseconds, virtually instantaneous compared to nuclear resonant contributions. A “time-discrimination trick,” which is illustrated in Fig. 3, can cleanly separate nuclear resonant signals from other scattering contributions. The use of this time-discrimination trick makes Nrs techniques possible.

Scattering processes

A schematic of the excitation process of a nuclear resonance is shown in Fig. 1. For a description of Nrs, the de-excitation pathways must also be considered. The classification of elastic-inelastic and coherent-incoherent scattering processes is based on analysis of the initial and final quantum state of the scatterer symbolized by

$$|\Phi_i\rangle|\gamma_i\rangle \rightarrow |\Phi_n\rangle \rightarrow |\Phi_f\rangle|\gamma_f\rangle. \quad (2)$$

States of the x-ray field and the scatterer are described by $|\gamma\rangle$ and $|\Phi\rangle$, respectively. The intermediate state exists without x-ray photons. An inelastic scattering process is characterized by different energies of initial and final photon states, which implies an energy transfer to the scatterer. A meaningful definition of coherent and incoherent scattering can only be given for a collection of atoms, for which we may write

$$|\Phi_i\rangle = |\chi_i\rangle \prod_j |\phi_i^{(j)}\rangle. \quad (3)$$

Here $|\phi^{(j)}\rangle$ symbolizes a core state, i.e., the state of nucleus and inner electron shell, of atom j . The collective state of itinerant electrons and lattice vibrations is written as $|\chi\rangle$.

A classification of scattering processes using this nomenclature is presented in Fig. 4. Coherent processes leave all core states $|\phi^{(j)}\rangle$ unchanged. The scattering atom can in principle not be identified, and the situation is analogous to a quantum mechanical multi-slit experiment. The change of just one atom's state serves as an indicator, and the process will be incoherent. In particular, SMS is based on the coherent elastic process, whereas NRIXS originates from incoherent processes. Coherent inelastic scattering by resonant nuclei is of negligible strength. The almost purely incoherent character of inelastic NRS simplifies the interpretation of NRIXS data and presents a clear distinction to inelastic neutron scattering where incoherent and coherent processes often occur with similar strength.

NRIXS

The resonant absorption of an x-ray photon can lead to a simultaneous change of nuclear state and vibrational quantum state of the solid as illustrated in Fig. 5. Three energy scales determine the properties of this process: the transition energy of several keV; the phonon energies of the order of meV; the nuclear level width of less than μeV . The energies are different by many orders of magnitude, and energy eigenstates are very well described by simple combination of nuclear states and phonon states, e.g., $|g\rangle|1\rangle$ is a quantum state with the nucleus in the ground state and one phonon present. If we investigate the vibrating nucleus with monochromatic x rays, we would observe transitions with nuclear transition energy E_0 described by $|g\rangle|n\rangle \rightarrow |e\rangle|n\rangle$ and m-phonon creation of the type $|g\rangle|n\rangle \rightarrow |e\rangle|n+m\rangle$ leading to upshifted transition energies $E_0 + m\varepsilon$, where ε is the energy of the phonon. Also m-phonon annihilation of the type $|g\rangle|n\rangle \rightarrow |e\rangle|n-m\rangle$ with $n \geq m$ leads to downshifted transition energies $E_0 - m\varepsilon$. The absorption behavior is quantitatively described by the excitation probability density $S(E)$. The value of $S(E) dE$ gives the probability that the nucleus can be excited by x rays in the energy range $[E, E + dE]$. The phonon-creation/annihilation side bands of $S(E)$ are analogous to the Stokes and anti-Stokes lines observed by optical spectroscopies. The ratio $S(-E)/S(E)$ is universally given by the Boltzmann factor, i.e., $S(-E) = \exp[-\beta E]S(E)$, with $\beta = 1/(k_B T)$, temperature T , and Boltzmann's constant k_B . This relationship is known as “detailed balance” and is an intrinsic feature of all NRIXS spectra. The partial PDOS is extracted by a mathematical inversion procedure from $S(E)$. Here “partial” refers to the selection that has taken place by observing only vibrations of the resonant isotope.

Fig. 4 Classification scheme for scattering processes. Incoherent scattering implies energy transfer unless some core states are degenerate. Coherent inelastic NRS is of negligible strength.

Fig. 5 The influence of atomic vibrations on the nuclear level scheme. The nucleus is embedded in an Einstein solid with a specific phonon energy ε . This leads to sidebands in the excitation probability density $S(E)$ corresponding to phonon creation or annihilation.

Cross section

Excitation probabilities can be calculated with Fermi's Golden Rule which gives us the transition rate Λ_{ni} for changes from the initial state $|\Phi_i\rangle = |\chi_i\rangle|\phi_i\rangle$ to an intermediate state $|\Phi_n\rangle = |\chi_n\rangle|\phi_n\rangle$ under the influence of a monochromatic x-ray field of energy $\bar{E}$, amplitude $\mathbf{a}$, and wave vector $\mathbf{k}$

$$\Lambda_{ni} = \frac{2\pi}{\hbar} \left| \langle \Phi_n | \hat{H}_{int} | \Phi_i \rangle \right|^2 \delta(E_{ni} - \bar{E}). \quad (4)$$

The energy difference of the states is given by E_{ni} , and the interaction Hamiltonian can be expressed by

$$\hat{H}_{int} = e^{ik \cdot \hat{\mathbf{r}}} \mathbf{a} \cdot \hat{\mathbf{J}}(-\mathbf{k}), \quad (5)$$

where $\hat{\mathbf{J}}$ is the spatial Fourier transform of the nuclear current operator in the center of mass frame, and the position of the center of mass is given by $\mathbf{r}$. We obtain for the cross section

$$\sigma(E, \mathbf{k}) = \frac{1}{|\mathbf{a}|^2} \sum_n \langle \Lambda_{ni} \rangle_i = \frac{\pi}{2} \sigma_N \Gamma S(E, \mathbf{k}), \quad (6)$$

where $E = \bar{E} - E_0$ is the energy of the incident x rays relative to the nuclear transition energy. The angle brackets indicate an average over all initial states that may be present, usually a thermal distribution. The last term is defined by

$$S(E, \mathbf{k}) = \int \frac{dt}{2\pi\hbar} e^{iEt/\hbar} \left\langle e^{ik \cdot \hat{\mathbf{r}}(t)} e^{-ik \cdot \hat{\mathbf{r}}(0)} \right\rangle. \quad (7)$$

This is the excitation probability density mentioned earlier, and here it is expressed as a self-correlation function of the position of a resonant isotope. For solid materials, $S(E, \mathbf{k})$ shows a sharp peak with width Γ around the nuclear transition energy E_0 , i.e., around $E = 0$. This peak originates in recoilless absorption of x rays by the nucleus which is also known as the Mössbauer effect. In fact, we may write $\Gamma S(0) = f$, the Lamb-Mössbauer factor or probability for recoilless absorption. The value of f varies approximately between 0.05 and 0.9 for solids at room temperature but vanishes for liquids and gases. The estimate for absorption "on resonance" is then.

$$\sigma(0) \approx \frac{\pi}{2} \sigma_N f. \quad (8)$$

With the exception of the elastic peak, we expect $S(E)$ to be a smooth function in energy extending over an energy range that may be estimated by the Debye energy Θ . From Eq. (7) we obtain $\int S(E) dE = 1$, and with this normalization we can estimate for the "off resonance" region $\Theta S(E) \approx 1 - f$ providing

$$\sigma(E \neq 0) \approx \frac{\pi}{2} \sigma_N (1-f) \frac{\Gamma}{\Theta}. \quad (9)$$

A quantitative estimate for ^{57}Fe in metallic form gives in units of the photoelectric cross section

$$\sigma(0) \approx 560 \sigma_{pe} \quad \sigma(E \neq 0) \approx 0.0002 \sigma_{pe}. \quad (10)$$

The change of cross section by six orders of magnitude when moving away from the transition energy is dramatic. The large “on resonance” value permits conventional energy-resolved Mössbauer spectroscopy. The observation of the phonon sidebands via the small “off resonance” value requires the use of time discrimination.

Observation

Let us imagine a resonant nucleus that was somehow excited. The nucleus will decay into the ground state either by emission of an x-ray photon or by transferring the excitation energy to the electron shell. In the latter case, an electron is expelled, and the hole is quickly filled by other electrons with the emission of fluorescence x rays. All these decay products are emitted with some delay relative to the time of excitation of the nucleus, and the average delay time is given by the natural lifetime. Fig. 3 illustrates the time evolution of the scattered intensity of a material containing resonant nuclei after excitation with a SR pulse. If the energy of the incident x ray is close to the nuclear transition energy, nuclei are excited, and delayed emission of x rays can be observed. If only the delayed photons are counted while tuning the energy of the incident x-ray pulses, we expect to measure an event rate that is proportional to $\sigma(E)$. The normalized data then provide $S(E)$. An example of data collected from a metallic foil of ^{57}Fe is shown in Fig. 6. The low background shows that the time-discrimination trick removes all non-nuclear scattering of the x rays very effectively.

Phonon density of states

In many cases, an expansion of the interatomic potential around the equilibrium positions of the atoms in a solid is quite accurately described by a quadratic dependence on the atomic displacements. In this quasi-harmonic approximation, the equation of motion for the atomic motions can be integrated. The excitation probability can then be rewritten in a physically meaningful way as

$$\begin{aligned} S(E) &= f \delta(E) + \sum_{n=1} S_n(E) \\ S_1(E) &= \frac{f E_R}{E(1 - \exp(-\beta E))} g(|E|) \\ S_n(E) &= \frac{1}{nf} \int S_{n-1}(E') S_1(E - E') dE', \end{aligned} \quad (11)$$

where the individual terms S_n correspond to n-phonon contributions. The delta-distribution term describes elastic scattering. The probability for this process is described in terms of the Lamb-Mössbauer factor f . The probability dP_1 to create ($E > 0$) or annihilate

Fig. 6 Phonon excitation probability density from NRIXS data of an iron foil at two temperatures. Energy zero corresponds to the nuclear transition energy of 14.4125 keV of the ^{57}Fe isotope. At low temperatures phonon annihilation (negative energy values) is inhibited.

Fig. 7 The PDOS of iron metal (bcc) at two temperatures. The curves show $3g$ calculated from the data shown in Fig. 6 using Eq. (11).

($E > 0$) one phonon of energy E is given by the first-order term, i.e., $dP_1 = S_1(E)dE$. The second-order term incorporates the participation of two phonons with energies that add to E . For a given inverse temperature β , all terms in Eq. (11) are generated from the PDOS $g(E)$. The measurement provides $S(E)$, and an inversion of Eq. (11) gives $g(E)$. In Fig. 7, we show the PDOS of iron metal.

SMS

In solids the probability that NRs occurs without change in the vibrational state is often appreciable and was introduced previously as the Lamb-Mössbauer factor f . In terms of the phonon excitation probability density of Eq. (7), we have $f = \Gamma S(0)$ with corresponding transitions indicated in Fig. 5. Now that vibrational transitions are excluded, slight energy differences of the nuclear levels become visible and measurable. The nuclear level splitting is caused by the electronic environment and is known as hyperfine interaction. The exclusion of phonon excitations results in elastic coherent scattering. This process is described by a differential scattering cross section that is strongly peaked in certain directions and in particular the direction of the incident x rays (nuclear forward scattering.)

Level splitting

Fig. 8 shows a ^{57}Fe nucleus under the influence of an electric field gradient (EFG) or a magnetic field. The energy levels of the isolated nucleus are twofold and fourfold degenerate, respectively. The presence of an EFG, which is created by the electronic environment and couples to the quadrupole moment of the nucleus, partly removes the degeneracy. In case of an axially symmetric EFG, the energy splitting for spin quantum numbers $I > 1/2$ and $m = -I, \dots, I$ is given by

$$E_m = \Delta \frac{3m^2 - I(I+1)}{2I(2I-1)}, \quad (12)$$

where Δ is called the electric quadrupole splitting. For the ^{57}Fe case, we obtain a characteristic two-line pattern with $E_{\pm 3/2} - E_{\pm 1/2} = \Delta$.

The presence of the magnetic field imprints unidirectional symmetry, which removes the degeneracy completely. The energy splittings are given by

$$E_m = -\mu B \frac{m}{I} \quad m = -I, \dots, I, \quad (13)$$

where μ , I are the magnetic moment, spin of the nuclear state, B is the magnetic field at the nucleus, and m is the spin-projection quantum number. The 14.4125 keV transition of ^{57}Fe has M1 multipolarity, and the individual transitions shown in Fig. 8 follow dipole selection rules, i.e., $|m_e - m_g| \leq 1$. This results in a characteristic six-line pattern.

In addition to the interactions discussed above, one expects a renormalization of the energy of nuclear levels due to the presence of s-electrons in the nuclear volume. The observable result is a slight shift of the transition energy that is proportional to the density of the s-electrons in the nuclear volume. This so-called isomer shift can only be measured by comparison of different materials, e.g., for ^{57}Fe the isomer shift is usually given relative to ^{57}Fe nuclei in iron metal at ambient conditions.

Fig. 8 Nuclear level splitting of ^{57}Fe by interactions with electrons. The presence of an EFG or a magnetic field leads to several nuclear transitions separated by up to several μeV . The ground and excited state have spin quantum numbers of 1/2 and 3/2, respectively.

Index of refraction

SMS is an elastic coherent process, and all possible nuclear sublevels can be excited simultaneously by a short x-ray pulse with sufficient bandwidth. The different nuclear transitions are then analogous to a set of oscillators with slightly different energies that are excited in phase at a given instant. Shortly after the x-ray pulse has passed, the de-excitation begins, also in phase, but soon the increasing phase difference leads to destructive interference and then again to a constructive interference. This process leads to oscillations in the emission of the scattered radiation that depend directly on the nuclear level splitting and thus on the hyperfine interactions.

In a transmission geometry, SMS is usually described by an energy-dependent contribution to the index of refraction

$$n(E) = \frac{\hbar c}{2E} \rho \sigma_N f \sum_l \frac{W_l}{z_l(E) - i}, \quad (14)$$

where ρ is the number density of resonant nuclei, σ_N is the nuclear resonant cross section, and f is the Lamb-Mössbauer factor. The sum is over all sublevels of nuclear ground and excited states. The function $z_l = 2(E_l - E)/\Gamma$ depends on the energy difference between excited and ground states E_l and the nuclear level width Γ . The weight of each resonance is given by W_l with the normalization $\sum_l W_l = 1$. The weights depend on the directions of the hyperfine fields relative to the direction and the polarization of the SR. For simplicity we ignore their tensor character. Then the transmission of monochromatic x rays of energy E through a sample of thickness D is given by

$$T(E) = T_0 \exp \left[-\eta \sum_l \frac{W_l}{z_l^2(E) + 1} \right], \quad (15)$$

where $\eta = \rho \sigma_N f D$ is called "effective thickness" of the platelet. The factor T_0 accounts for electronic absorption. The time response to a SR pulse is expressed by

$$\frac{dI}{dt} = T_0 \tau \left| \mathcal{F} \left(\exp \left[i \frac{\eta}{2} \sum_l \frac{W_l}{z_l(E) - i} \right] - 1 \right) \right|^2, \quad (16)$$

Fig. 9 SMS spectra in energy and time. Calculations used Eqs. (15) and (16) with small ($\eta = 1$, solid lines) and large ($\eta = 50$, dashed lines) effective thicknesses. Panel (A) displays the case without hyperfine fields; panels (B) and (C) show spectra characteristic for an EFG and a magnetic field, respectively. Time spectra (right side) were normalized to identical area.

where $\mathcal{F}$ symbolizes Fourier transformation. The primary application of SMS is the determination of hyperfine interaction parameters. The transmission spectra are easier to interpret if the effective thickness is small. Large values of η lead to a self-absorption effect, i.e., a broadening of the absorption lines in the energy spectra and a faster decay in the time spectra accompanied by aperiodic oscillations. The influence of the effective thickness is demonstrated in Fig. 9 by calculations using Eqs. (15) and (16).

Experimental procedure

A schematic of the typical experimental setup that can be found at third-generation SR facilities is shown in Fig. 10. The x-ray source consists of electron bunches that are orbiting in the storage ring and periodically pass through an undulator. The x rays are monochromatized in two steps using a premonochromator and a high-resolution monochromator.

For NRIXS measurements, the energy bandwidth determines the resolution of the phonon spectra of the samples. The high-resolution monochromator is tuned around the nuclear transition energy, and the x rays excite the nuclei in the sample. The re-emitted radiation is observed with an avalanche photodiode detector that is placed as close as possible to the sample but away from any strong coherent scattering directions. The integrated delayed counting rate is recorded.

For SMS measurements, the energy bandwidth should be as small as practicably achievable with reasonable efficiency. The high-resolution monochromator is tuned to the nuclear transition energy and kept as stable as possible. X rays that are transmitted through the sample excite the resonant nuclei coherently and are observed with an avalanche photodiode detector that is placed far enough away from the sample to avoid contamination from incoherent scattering. The delayed events are mapped as a function of elapsed time between arrival of a SR pulse and detection of transmitted x-ray photon - this constitutes the time spectrum of the nuclei in the sample.

Fig. 10 Experimental setup for NRIXS and SMS.

Conclusion

The discovery of NRS using a synchrotron radiation source by Gerdau et al. (1985) was followed by an intense development phase that was fueled by availability of new third-generation SR facilities. A variety of NRS techniques was explored during the earlier period but mostly SMS and NRIXS introduced in this section have survived the test of practicality. SMS and NRIXS find unique applications to a variety of problems in condensed-matter physics, material science, geophysics, biophysics, and chemistry. Early NRS studies showed that its SR based form greatly benefitted from a new, translational approach: time resolved instead of energy resolved measurements, the latter familiar in traditional Mössbauer spectroscopy. This advance resulted from the time structure of SR, which is emitted as a sequence of very short x-ray pulses of typically less than 100 ps duration. Time resolved spectra are almost background-free and therefore show a vastly superior signal-to-noise ratio compared to energy resolved measurements leading to unique applications.

Today's evolution of SR sources is focused on optimized x-ray brilliance realized in either "ultimate storage rings" or "X-ray lasers." Experiments at the latter source are extremely access limited and will probably not play a major role for NRS techniques. The first source is an upgrade of existing SR facilities to achieve the smallest possible electron emittance in the storage ring and, in combination with optimized undulators, very high x-ray brilliance with significant transverse coherence. This often seems to require a time structure that puts NRS experiments at a disadvantage: x-ray pulse spacings that are too small for time-resolved studies. This leaves experimenters with time-integrated techniques with substantially reduced signal-to-noise ratios for SMS and reduced counting rate for NRIXS experiments. These issues are partially compensated by the improved x-ray properties that permit improvements in x-ray optics.

NRS techniques are adapting to x-ray source developments and SMS and NRIXS as introduced in this section are expected to dominate the selection. NRS may be considered a *gem* under a multitude of spectroscopic techniques and certainly contributes to the diversity of SR-based x-ray spectroscopies.

Abstract

This review discusses the physical origin of elastic scattering of radiation (Rayleigh Scattering, RS), its relation to fluctuations in fluids and fluid mixtures, its role in the investigation of dispersions of colloidal particles. Particular emphasis is put on the Optical Theorem, which allows to relate the total RS cross section to the real and imaginary part of the refractive index. Recent advances concerning RS from degenerate quantum gases, from correlated fluids, and from suspensions of interacting particles, are presented. Finally, a brief introduction to quasi-elastic RS is given, also known as Dynamic Light Scattering, is given, together with a mention of novel techniques that blend scattering and imaging.

Introduction

Rayleigh scattering (RS) is the elastic spreading of electromagnetic radiation from bound electrons, after they have been excited to virtual states far from resonances. Therefore, it differs from resonant fluorescence, molecular Raman scattering, and Brillouin scattering in condensed media, which are discussed elsewhere in this encyclopedia. Thomson scattering can be seen as a particular case of RS from free electrons, but is not further discussed in this article (neither is its relativistic Compton counterpart). Molecular RS plays a primary role in atmospheric optics accounting for the blue color of the sky and a large number of optical phenomena ranging from rainbows to fogbows, glories, halos, coronae, blue sun and moon, and the white color of clouds and snow, to cite only a few. A comprehensive discussion of atmospheric scattering has been made by Minnaert (1954) and, more recently, by Lynch and Livingston (1995).

Yet, the most interesting applications of RS arguably concern scattering from mesoscopic objects, either in the form of aerosols or suspensions of colloidal particles with a size ranging from a few nanometers to a few micrometers. Scattering from pollutant airborne particles has, for instance, crucial consequences on re-irradiation of solar energy from the lower atmosphere. Measurements of the scattering properties of dispersed particles yield primary information on colloid size, morphology, and interactions. Chances of obtaining photonic bandgap crystals often rely on the peculiar scattering properties of metal-coated colloids. Finally, by exploiting radiation forces associated to scattering, particles can be easily manipulated using noninvasive “optical tweezers,” allowing one to design template surfaces of interest in photonics. Although, fluid systems are primarily dealt with, it is also important to point out that the attenuation due to RS sets severe limits to the useful wavelength range for light propagation in optical fibers.

This article is organized as follows. After a basic analysis of elastic molecular scattering, the key role of fluctuations in RS from condensed media is pointed out, and a fluctuation approach to shortly derive RS from simple fluids and mixtures is applied. The final and largest part is devoted to particle RS and its exploitation. Besides specific applications, however, the main message of which an attempt is made to convey is the following: “every deviation of light from rectilinear propagation, including diffraction and even geometrical refraction, can be ultimately seen as a consequence of Rayleigh scattering.” As will be seen, the optical theorem, linking the refractive index to scattering properties, and the large particle limit of Mie scattering, yielding classical diffraction and eventually geometric optics, justify this strong statement.

Molecular Rayleigh scattering

First, recall the basic geometry of a scattering experiment. As incident field, what will always be taken is a plane wave linearly polarized along $\hat{n}_i$ having a wave vector $\mathbf{k}_i$, with $|\mathbf{k}_i| = k = 2\pi/\lambda$, where λ is the wavelength in the medium. Measurements consist in detecting the light scattered along the direction set by the wave vector $\mathbf{k}_s$ that, together with $\mathbf{k}_i$, fixes the scattering plane. Since Rayleigh scattering is elastic, one must have $|\mathbf{k}_s| = k$, hence the scattering vector $\mathbf{q} \doteq \mathbf{k}_i - \mathbf{k}_s$ has magnitude $q = (4\pi/\lambda) \sin(\vartheta/2)$, where ϑ is the angle in the scattering plane between $\mathbf{k}_i$ and $\mathbf{k}_s$, while the azimuth angle with respect to the normal to the scattering plane will conversely be denoted by φ . In some measurements, a specific polarization component of the scattered field along $\hat{n}_s$ may be selected with a polarizer.

The simplest way to estimate elastic scattering is the elegant dimensional argument originally devised by Rayleigh¹ that, restated in modern terms, goes as follows. If the size of the scattering objects is much smaller than λ , so that they essentially 'see' a spatially uniform, time-varying field, the scattered and incident fields will be proportional. Their dimensionless ratio E_s/E_i may in principle depend on λ , the speed of light c , the volume V of a scatterer, the dielectric constants ϵ_p , ϵ_m of the materials constituting the particle and the surrounding medium, and the distance r of the observation point from the scattering volume. Since c is the only quantity that contains time, it should not appear in E_s/E_i . Similarly, ϵ_p and ϵ_m must appear only as a homogenous function f of the ratio ϵ_p/ϵ_m . Since molecular polarizability α is linearly proportional to V , so must be E_s . Finally, in the radiation zone the scattered field will be a spherical wave, so that $E_s \propto r^{-1}$. Therefore, the simplest dimensionless combination is $E_s/E_i = Vr^{-1}\lambda^{-2}f(\epsilon_p/\epsilon_m)$, and for the scattered intensity one must have

$$I_s = \frac{V^2}{r^2\lambda^4} f^2\left(\frac{\epsilon_p}{\epsilon_m}\right) I_0, \quad (1)$$

giving both a strong preferential scattering of short wavelengths (accounting for the hue of the sky and for the sun reddening at dawn and setting) and the remarkable dependence on molecular volume (yielding, for spheroidal molecules, a sixth power dependence on the radius).

For a molecular scatterer of size $d \ll \lambda$, a formal analysis can be performed by solving the Helmholtz equation for the vector potential in far-field (radiation) zone $r \gg \lambda \gg d$, expanding the solution in multipoles, and retaining only the lowest (electric dipole) order. Within this approximation, the incident field induces a dipole $\mathbf{p} = \boldsymbol{\alpha} \cdot \mathbf{E}_i$, where in general the molecular polarizability $\boldsymbol{\alpha} = \alpha_{ij}$ is a tensor (so that $\mathbf{p}$ and $\mathbf{E}_i$ are not necessarily parallel). The induced dipole irradiates a spherical wave at the same frequency and with amplitude given by

$$\mathbf{E}_s(\mathbf{r}) = \frac{k^2}{4\pi\epsilon_0} (\hat{\mathbf{r}} \times \mathbf{p} \times \hat{\mathbf{r}}) \frac{\exp(ikr)}{r}. \quad (2)$$

If, for simplicity, one assumes that the molecule has a scalar polarizability α , so that $p \equiv |\mathbf{p}| = \alpha E_i$, the scattered intensity (irradiance) is given by

$$I_s = \frac{\epsilon_0 c}{2} \overline{\mathbf{E}_s^* \mathbf{E}_s} = \frac{\pi^2 \alpha^2 \sin^2 \gamma}{\epsilon_0^2 \lambda^4 r^2} I_0 \quad (3)$$

where I_0 is the incident intensity, and γ is the angle between $\mathbf{p}$ and the direction of propagation of the scattered field.

This simple classical analysis is fully adequate for treating most of the problems involving molecular RS. For what concerns quantum effects, what must be first noticed is that RS is a two-photon process requiring full quantization of the radiation field. A simple quantum analysis of RS can be made starting from two-level Bloch equations, or from a more general multi-level perturbation theory leading to the Kramers-Heisenberg formula, which has the advantage of treating on the same footing Rayleigh, Thomson, and inelastic Raman scattering, and accounts also for quantum corrections to classical RS cross-sections (see Loudon, 2000). Nevertheless, far from resonances these corrections are negligible, so that a fully classical approach will be used in what follows.

Scattering and fluctuations

The former single-scatterer approach to RS may however be misleading, since it misses a crucial point. Indeed, a *uniform* distribution of molecules will not scatter light *at all*, since the phases of the scattered fields are uniformly distributed in $[0, 2\pi]$. Therefore, the total scattered field vanishes for all except the forward direction where, adding to the incident beam, leads to a phase delay of the transmitted beam modifying (as shall be better seen below) the refractive index of the medium. Exceptions are ordered arrays of scatterers, where Bragg peaks appear due to breaking of continuous translational symmetry. Scattering therefore always require *fluctuations*.

A very general approach to the problem can be made by treating the scattering medium as a continuum where, in order to account also for optical anisotropy effects, local dielectric (and therefore, refractive index) fluctuations are introduced by means of a tensor $\delta\epsilon(\mathbf{r}, t)$, and deriving a wave-propagation equation in weakly inhomogeneous media. By assuming that the scattered field is much smaller than the incident field, the dielectric fluctuations in spatial Fourier components can be decomposed as

¹Lord Rayleigh (John William Strutt) developed his theory in a series of papers, culminating in a final masterpiece, see Rayleigh (1899).

$$\delta\epsilon(\mathbf{q}, t) = \int \delta\epsilon(\mathbf{r}, t) e^{i\mathbf{q}\cdot\mathbf{r}} d^3r, \quad (4)$$

where $\mathbf{r}$ gives the position of the scattering element with respect to an arbitrary origin O in the scattering volume. The instantaneous scattered field amplitude reaching a detector placed at a distance R from O , after passing through a polarizer with transmitting axis set along $\hat{\mathbf{n}}_f$, is given by

$$E_s^{if}(R, t) = -\frac{k^2 E_0}{4\pi\epsilon_0 R} \delta\epsilon_{if}(q, t) e^{i(kR - \omega t)}, \quad (5)$$

where $\delta\epsilon_{if} \equiv \hat{\mathbf{n}}_i \cdot \delta\epsilon(\mathbf{q}, t) \cdot \hat{\mathbf{n}}_f$. The time-averaged detected intensity is

$$I_s^{if}(\mathbf{q}) = \frac{k^4 I_0}{16\pi^2 \epsilon_0^2 R^2} \langle |\delta\epsilon_{if}|^2 \rangle, \quad (6)$$

and is therefore proportional to the mean square fluctuations of the dielectric constant with the same spatial frequency $\mathbf{q}$.

In order to find a connection with the molecular approach, which is particularly useful when dealing with scattering from dispersed particles, it can simply be assumed that the local dielectric constant depends explicitly only on the local molecular number density $\rho(\mathbf{r}, t)$ (see the next section for a discussion) writing $\delta\epsilon(\mathbf{r}, t) = \boldsymbol{\alpha}(t)\rho(\mathbf{r}, t)$, where $\boldsymbol{\alpha}(t)$ is the molecular polarizability tensor, which depends on time too because of molecular rotations (See section “[Scattering from dispersed particles](#)” for details). Expressing the local density fluctuations as a sum of delta functions over the molecular positions $\mathbf{r}_i(t)$ as $\delta\rho(\mathbf{r}, t) = \sum_i \delta(\mathbf{r} - \mathbf{r}_i) - \bar{\rho}$, where $\bar{\rho}$ is the average number density, and putting $\alpha_{if}(t) \equiv \hat{\mathbf{n}}_f \cdot \boldsymbol{\alpha}(\mathbf{q}, t) \cdot \hat{\mathbf{n}}_f$, one can immediately see that

$$\delta\epsilon_{if}(\mathbf{q}, t) = \alpha_{if}(t) \left\{ \sum_i \exp[i\mathbf{q} \cdot \mathbf{r}_i(t)] - N\delta(q) \right\},$$

where the second term (coming from $\bar{\rho}$) is simply the scattering contribution at $q = 0$ from the N molecules.

Provided that molecular orientations and translations are uncorrelated (so that the amplitude and phase averages factorize), from Eq. (6) one therefore obtains

$$I_s^{if}(\mathbf{q}) = \frac{k^4 N I_0}{16\pi^2 \epsilon_0^2 R^2} \langle |\alpha_{if}|^2 \rangle S(q), \quad (7)$$

where

$$S(q) = N^{-1} \sum_{i,j} \langle \exp[i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)] \rangle \quad (8)$$

is the static *structure factor*. To make things clearer, consider an ideal gas where particle positions are uncorrelated. Then $\langle \exp[i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)] \rangle = \delta_{ij}$, so that $S(q) = 1$ and I is proportional to N . Notice that this apparently ‘trivial’ scaling with N , holds true only because (Poisson) density fluctuations in an ideal gas are proportional to $\sqrt{N}$: for interacting systems, it is no longer so.

Rayleigh scattering from pure fluids and fluid mixtures

Simple liquids

In liquids, fluctuations of the local dielectric constant can be expanded in terms of any two thermodynamic variables whose fluctuations are uncorrelated (see [Landau et al., 1990](#)), like for instance temperature T and density ρ . Since experimentally, for most simple liquids, $(\partial\epsilon/\partial T)_\rho \approx 0$, RS is in fact mostly due to density fluctuations. In order to derive RS effects in simple fluids, it is however more convenient taking pressure p and entropy S as independent variables, and using of a fluctuating hydrodynamics approach. This amounts to linearizing for small fluctuations the continuity, Navier-Stokes, and heat equations and finding their normal modes ([Berne and Pecora, 1976](#)).

Since in the continuity equation ρ is coupled to the fluid velocity $\mathbf{v}$ only through $\nabla \cdot \mathbf{v}$, density fluctuations are uncoupled to transverse velocity modes, which therefore cannot be detected by light scattering. In addition to two propagating pressure modes (corresponding to absorption or excitation of sound waves, giving rise to Brillouin scattering), the solution of linearized mode equations yields a thermal diffusive mode, corresponding to the frequency-unshifted Rayleigh peak having a width $\Delta\omega = D_T q^2$, where D_T is the thermal diffusivity, and an amplitude proportional to the difference $c_p - c_v$ of the specific heats at constant pressure and volume. For many liquids, and in particular for water, $c_p - c_v$ is rather small, and therefore RS fairly weak.²

It is also useful to point out that the structure factor defined in (8) can directly be linked to structural correlations ([Piazza, 2017](#)). Introducing the density autocorrelation function for a homogeneous (but not necessarily isotropic) fluid

²In spite of a widespread belief, the bluish appearance of thick water layers or ice blocks is not primarily due to scattering, but to a much stronger absorption effect due to an overtone vibrational peak close to the red edge of the visible spectrum. Indeed, D_2O , where the shifts to higher λ due to isotope effects, is much more transparent.

$$G(\mathbf{r}) = \langle \rho(0)\rho(\mathbf{r}) \rangle - \rho^2,$$

where $\rho(\mathbf{r})$ is the local density, with $\rho = \langle \rho(\mathbf{r}) \rangle$, one indeed has

$$S(\mathbf{q}) = \frac{1}{\rho} \int G(\mathbf{r}) \exp(i\mathbf{q} \cdot \mathbf{r}) d^3r, \quad (9)$$

so that $S(\mathbf{q})$ is essentially the (inverse) spatial Fourier transform of $C(\mathbf{r})$. Since the latter is related to the pair distribution function $g(\mathbf{r})$, the probability density per unit volume of finding two particles at a distance $\mathbf{r}$, by

$$G(\mathbf{r}) = \rho \delta(\mathbf{r}) - \rho^2 [g(\mathbf{r}) - 1],$$

where the first term is the self-correlation of the local density, one finds

$$S(\mathbf{q}) = 1 + \rho \int [g(\mathbf{r}) - 1] \exp(i\mathbf{q} \cdot \mathbf{r}) d^3r \quad (10)$$

It is however important to recall that the typical q -range over which structural features of simple fluids develop is much larger than the range probed by light scattering, which therefore essentially measures only $S(0) = \rho k_B T \chi_T$, where $\chi_T = (1/\rho)(\partial P/\partial \rho)^{-1}$ is the isothermal compressibility. As discussed in what follows, the situation is however very different for suspensions of mesoscopic particles, where the structural spatial scales are often of the order λ .

Liquid mixtures and solutions

In liquid mixtures or molecular solutions new modes appear due to the presence of an additional conserved variable, namely the concentration c of one of the two species, adding a hydrodynamic mass diffusion equation. The analysis is much simpler if pressure fluctuation, and therefore effects on Brillouin peaks, are neglected (see [Berne and Pecora, 1976](#)), so that the problems amount to solving by Laplace transform the linearized form of the coupled equations for the fluctuations δc , δT

$$\begin{aligned} \frac{\partial(\delta c)}{\partial t} &= D \left[\nabla^2(\delta c) + \frac{k_T}{T} \nabla^2(\delta T) \right] \\ \frac{\partial(\delta T)}{\partial t} - \frac{1}{c_p} K_T \left(\frac{\partial \mu}{\partial c} \right) \frac{\partial(\delta c)}{\partial t} &= D_T \nabla^2(\delta T), \end{aligned} \quad (11)$$

where D is the mass diffusion coefficient, μ is the chemical potential of the mixture, and k_T is the thermal diffusion ratio, quantifying coupling of mass and heat transport through the Soret effect. Solution of (11) yields two diffusive modes where thermal and concentration fluctuations are in general mixed: in practice, however, since $D \ll D_T$ (for most liquids $D_T \simeq 10^{-3} \text{ cm}^2 \text{ s}^{-1}$, while D varies between $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for simple mixtures and $10^{-6} - 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ for macromolecular solutes) the two modes are almost decoupled. The peak due to concentration fluctuation has an extremely narrow width $\Delta\omega = Dq^2$ and an amplitude proportional to $(\partial\mu/\partial c)^{-1}$. The role played by density fluctuations in simple fluids is then taken by concentration fluctuations. For dilute solutions, this means that RS is proportional to the osmotic compressibility.

Quantum fluids

Although this paper mainly addresses classical systems, it is worth giving some basic ideas concerning the scattering properties of fluids at temperatures and densities where quantum degeneracy effects become relevant. Particularly interesting is the strong suppression of RS in ultracold Fermi gases, an effect predicted several decades ago (see, for instance, [Javanainen and Ruostekoski, 1995](#)) but only very recently observed (see [DeMarco and Thywissen, 2021](#) and references therein).

Grasping the physical origin of this effect, often dubbed “Pauli blocking of light scattering”, is not difficult. At temperatures $T \ll T_F$, where T_F is the Fermi temperature, the Fermi-Dirac distribution is very close to a step function, and fermions “pile up” occupying the single-particle energy states up to the Fermi energy $\varepsilon_F = k_B T_F = \hbar^2 k_F^2 / 2m$, where $k_F \simeq (6\pi\rho/g_s)^{1/3}$ is the Fermi momentum at particle number density ρ and $g_s = 2s + 1$ is the spin degeneracy. Particles lying well within the “Fermi sea”, namely with a momentum k_0 consistently lower than k_F , will never be able to scatter radiation at wave vector q if the transferred momentum $\hbar q < k_F - k_0$, simply because they cannot find any available free state.³ Hence, RS is strongly suppressed and can occur only close to the Fermi surface.

A more quantitative way to explain the effect is based on considering that the Pauli exclusion principle introduces effective repulsions between fermions, even when they do not interact via “real” forces. As a consequence, a system of independent fermions will display pair correlations manifested by specific features of the structure factor. In the weakly-degenerate limit $\rho\Lambda^3 \ll 1$, where $\Lambda = h/\sqrt{2\pi m k_B T}$ is the thermal wavelength for fermions of mass m at temperature T , the pair correlation function becomes

³Currently, ultracold fermions at densities exceeding 10^{15} cm^{-3} can be reached, corresponding to a Fermi momentum of the order of $2 \times 10^5 \text{ cm}^{-1}$. In the visible range, this is far larger than the maximum scattering wave vector $4\pi/\lambda$.

$$g(r) = 1 - \exp(-2\pi r^2/\Lambda^2), \quad (12)$$

namely, $g(r)$ just display an “antibunching hole” up to interparticle distances of the order of Λ , which is the quantum equivalent of a hard-core repulsion for a classical system.⁴ The corresponding structure factor,

$$S(q) = 1 - \frac{\rho\Lambda^3}{2\sqrt{2}} \exp\left[-\frac{(q\Lambda)^2}{8\pi}\right], \quad (13)$$

has then a shallow minimum at $q = 0$ yielding an isothermal compressibility that coincides with the value obtained from the equation of state for a weakly-degenerate Fermi gas $P = nk_B T(1 + \rho\Lambda^3/4\sqrt{2})$.

Analytic expressions for $g(r)$ and $S(q)$ for lower temperature do exist, but in the case of fermions they are valid only for negative values of the chemical potentials, namely for $T \gg T_F$. Yet, the asymptotic limits for $T \rightarrow 0$ in Bosse et al. (2011) and numerical results in Tsutsui and Kita (2016) confirm that a system of highly degenerate fermions scatter almost no radiation in a q -range that extends up to Λ^{-1} , while recent experiments by Margalit et al. (2021), where temperatures down to $T \approx 0.2T_F$ were investigated, have indeed shown a reduction of RS up to 40%.

Scattering from dispersed particles

Statement of the problem

The important case of elastic scattering from dispersed particles is discussed here, first considering only particles made of an optically isotropic material, that is with a scalar polarizability. In far field, the scattered field $E_s(r, t)$ is an amplitude-modulated spherical wave, which can be written as

$$E_s(r, t) = s(\vartheta, \varphi) \frac{\exp[i(kr - \omega t)]}{ikr} E_0, \quad (14)$$

where $s(\vartheta, \varphi)$ is a dimensionless (single-particle) *scattering function*, which is in general a complex quantity, $s \doteq f(\vartheta, \varphi) \exp[i\phi(\vartheta, \varphi)]$.⁵ The scattered intensity can therefore be written in terms of the incident intensity I_0 as

$$I = \frac{f(\vartheta, \varphi)^2}{k^2 r^2} I_0. \quad (15)$$

By integrating $r^2 I_s$ over the solid angle Ω , the scattering cross-section for a single particle is therefore found to be

$$\sigma_s = \frac{1}{k^2} \int f^2(\vartheta, \varphi) d\Omega. \quad (16)$$

If, besides scattering, the particle absorbs part of the radiation with an absorption cross-section σ_a , the total extinction cross section will be given by $\sigma_{ext} = \sigma_s + \sigma_a$.

The previous definition can be generalized to account for scattering from optically anisotropic particles by writing

$$\begin{bmatrix} E_s^\perp \\ E_s^\parallel \end{bmatrix} = \frac{\exp[ik(r - z)]}{ikr} \begin{bmatrix} s_1 & s_2 \\ s_3 & s_4 \end{bmatrix} \begin{bmatrix} E_i^\perp \\ E_i^\parallel \end{bmatrix} \quad (17)$$

where z is the particle coordinate along the direction of the incident beam with respect to an arbitrary origin. Specific forms for the scattering matrix $[s_{ij}]$ are dictated by particle symmetry: for instance, it is diagonal for spherical particles made of an optically isotropic material and symmetric for nonchiral particles (van de Hulst, 1968).

The optical theorem (OT)

A simple, but extremely useful relation, which holds true not only for electromagnetic radiation but also for matter waves (Newton, 1976), connects the total scattering cross section to the scattering amplitude in the forward direction. The effect on the transmitted wavefront of the transit through a scattering medium can be expressed by stating that the forward scattering pattern consists in a faithful reproduction of the incident field that spatially superimposes with the transmitted radiation, but with a different phase. The interference between this “simulacrum” of the incident field and the portion of the field which passes through the medium without being scattered yields *both* its phase delay in traversing the medium (thus fixing its refractive index) and, adding any structural correlations, and (b) the incident to the non-radiative power loss due to absorption, field “seen” by a particle coincides with the

⁴For a weakly-degenerate Bose gas, the corresponding expression is $g(r) = 1 + \exp(-2\pi r^2/\Lambda^2)$, which conversely shows the boson propensity to “bunching” (Jeltes et al., 2007). It is however worth noticing that this result is somehow academic, since it is valid only for elementary massless bosons. Massive bosons are necessarily *composite*, namely, atoms with an even number of neutrons that definitely show a hard-core *repulsion* when their electronic clouds overlap.

⁵By factoring out an imaginary unit, which is related to the Gouy phase shift accumulated in far-field between a spherical and a plane wave, the amplitude function coincides in the short-wavelength limit (aside from polarization effects) with a standard normalized diffraction pattern (van de Hulst, 1968).

extinction of the power reduction of the transmitted field. For natural radiation, which loosely means that “multiple scattering” effects are negligible, this is explicitly treated in the so-called *Optical Theorem* (OT).

Consider again the simple case of a plane wave with incident wave vector $\mathbf{k}_i$ and polarized with the electric field along $\mathbf{n}_i$, which encounters a scattering and absorbing medium confined in a finite region of space around the origin. Then, the OT states that the extinction cross section is given by

$$\sigma_{ext} = \frac{4\pi}{k^2} (\mathbf{n}_i \cdot \mathbf{n}_s) \text{Re} [S(\mathbf{k}_s = \mathbf{k}_i)], \quad (18)$$

where $S(\mathbf{k}_s = \mathbf{k}_i)$ is the *overall* scattering function of the medium in the forward direction $\mathbf{k}_i$. This rather surprising result, which basically shows that evaluating the total extinction (due to scattering and, possibly, absorption) of the radiation traversing the medium requires to know *only* the forward scattering amplitude, can be rather easily obtained [Jackson \(1998\)](#) by considering that, at steady state, the change in the total energy density within a spherical region containing the whole scattering medium is solely due to the dissipative absorption processes taking place within it, and by equating the latter to the outward flux of the incident plus scattered energy.

The forward scattering amplitude, however, contains more information than what is simply conveyed by the OT, since the effects of propagation can be fully embodied into a complex refractive index $\tilde{n} = n + in'$, whose real and imaginary parts are respectively related to dispersion and power loss. Then, *both* n and n' can be formally linked to the real and imaginary parts of $S(\mathbf{k}_s = \mathbf{k}_i)$. Yet, such a relation is of little practical interest unless one is able to evaluate $S(\mathbf{k}_s = \mathbf{k}_i)$ in terms of the specific microscopic scattering and absorption events taking place in the medium. In the general case, this is a formidable task leading to cumbersome and rather impractical results. Nevertheless, for particle suspensions the complex refractive index of the whole dispersion can indeed be related to the scattering properties of the individual scatterers provided that (a) the particles interact very weakly, so they do not display any structural correlations, and (b) the incident field “seen” by a particle coincides with the *external* radiation, which loosely means that “multiple scattering” effects are negligible. If these conditions are met, then for a thin slab of a medium consisting of a dispersion of N identical isotropic scatterers illuminated by a monochromatic plane wave Eq. (18) reduces to

$$\sigma_{ext} = \frac{4\pi N}{k^2} \text{Re} [s(0)], \quad (19)$$

where $s(0)$ is the amplitude of the field scattered in the forward direction $\theta = 0$ by each *single* particle ([van de Hulst, 1968](#)).

The former simpler relation can be obtained by considering that for independent particles σ_{ext} is the sum of the single-particle cross sections, while in the forward direction (and *only* in this direction) the scattering amplitudes are additive too, because all scattering contributions add in phase, regardless of the particle positions. By evaluating the phase shift in propagation through the slab, the real and imaginary parts of the effective refractive index of the medium are then easily found to be

$$\begin{cases} n = 1 - \frac{2\pi\rho}{k^3} \text{Im}[s(0)] \\ n' = \frac{2\pi\rho}{k^3} \text{Re}[s(0)] \end{cases} \quad (20)$$

Hence the intensity of a plane wave propagating in the medium along z decreases as $I = I_0 \exp(-\gamma z)$, where the extinction coefficient

$$\gamma = 2kn' = \frac{4\pi\rho}{k^2} \text{Re} [s(0)] = \frac{\sigma_{ext}}{V} \quad (21)$$

is simply the extinction cross section per unit volume.

Scattering regimes

The full solution of the electromagnetic scattering for particles of arbitrary size and composition is very elaborate, even for the simplest case of homogeneous spheres. It is however useful considering some specific approximation yielding simple explicit expressions for the scattering function. For what follows, an important distinction is between the *external* incident field and the *internal* field within the particle. The refractive indices of the particle and of the surrounding medium (“solvent”) shall be denoted by n_p and n_s , the wavelength of the incident radiation *in vacuum* (so the wave vector is $k_{ext} = 2\pi n_s/\lambda_0$ for the external field, and $k_{int} = 2\pi n_p/\lambda_0$ within the particle) by λ_0 , and a characteristic particle size by a .

Particles small compared to the wavelength. This is what is called the Rayleigh regime in the strict sense. The defining requirement is that *both* the external and the internal fields are essentially uniform over the particle size. This means that the phase shifts ak_{ext} and ak_{int} have to be small, or $a \ll \lambda_0/2\pi n_s$, $a \ll \lambda_0/2\pi n_p$ (the second condition is generally more restrictive - notice in particular that it excludes strongly absorbing particles, whatever their size). The situation is then completely analogous to molecular Rayleigh scattering. If the particle is made by an optically isotropic material, so that its polarizability is scalar, the amplitude of the scattered field is given by Eq. (3) while, by integrating Eq. (3) and dividing by the incident intensity, the scattering cross section is found as

$$\sigma_s = k^4 \alpha^2 / 6\pi \epsilon_0^2. \quad (22)$$

A note of caution concerns however particle polarizability, which has to be interpreted as the *excess* optical polarizability with respect to an equal solvent volume. Noticing that, when the incident field is vertically polarized (perpendicular to the scattering plane), $\gamma \equiv \pi/2$, while if it is horizontally polarized $\gamma = \pi/2 - \vartheta$, the full scattering matrix is found to be

$$\mathbf{s} = \frac{ik^3\alpha}{4\pi\epsilon_0} \begin{bmatrix} 1 & 0 \\ 0 & \cos\vartheta \end{bmatrix}. \quad (23)$$

Specific expressions for the polarizability can be found by solving the electrostatic problem for a uniform field. For instance, for dielectric spheres of radius a , made of a material with dielectric constant ϵ_p ,

$$\alpha = 4\pi\epsilon_0 \frac{\epsilon_p/\epsilon_s - 1}{\epsilon_p/\epsilon_s + 2} a^3 = 4\pi\epsilon_s \frac{n_p^2 - n_s^2}{n_p^2 + 2n_s^2} a^3 \quad (24)$$

Since $s(0) = ik^3\alpha/4\pi\epsilon_0$, from the OT one has $\sigma_{ext} = (k/\epsilon_0) \text{Im}(\alpha)$, so that a reduction of the incident power should occur only for absorbing particles. This inconsistency derives from neglecting the Lorentz radiation reaction field, which is actually the *only* mechanism for power loss in the absence of non-radiative dissipation (Snider and Garcia-Lopez, 2006). Taking into account this contribution yields an imaginary term in the particle polarizability, which is modified as

$$\alpha \rightarrow \tilde{\alpha} = \alpha \left(1 + i\frac{2}{3}k^2\alpha \right). \quad (25)$$

Note that the additional term is *quadratic* in α . Taking into account radiation reactions, one finds that the complex refractive index $\tilde{n}$ of systems of point-like particles at number density ρ is exactly related to the modified polarizability defined in Eq. (25) by a *generalized Clausius-Mossotti (or Lorentz-Lorenz) relation*

$$\frac{\tilde{n}^2 - 1}{\tilde{n}^2 + 2} = \frac{4\pi}{3} \tilde{\alpha}\rho \quad (26)$$

It is useful to expand (26) at second order in $\tilde{\alpha}\rho$. Using (25) and equating the real and imaginary parts, one obtains

$$\begin{cases} n = 1 + 2\pi\alpha\rho + \frac{2}{3}(\pi\alpha\rho)^2 \\ n' = \frac{4\pi}{3}\rho k^3\alpha^2 \end{cases} \quad (27)$$

The real part coincides with the expansion at 2nd order of the usual Clausius-Mossotti formula, whereas the dissipative radiation-reaction term contribute *only* to attenuation. When this result is inserted into Eq. (20), it yields an explicit expression for the single-particle scattering amplitude

$$s_0(0) = \frac{2}{3}k^6\alpha^2 - ik^3\alpha, \quad (28)$$

and the correct extinction cross section $\sigma_{ext} = (8\pi/3)N\alpha^2k^4$ for RS from N independent particles with a size much smaller than λ .

Optically anisotropic particles. The previous result can be extended to small optically anisotropic particles. For simplicity, it is assumed that the particle is made of an uniaxial birefringent material. The polarizability tensor, referred to the particle optical principal axes X, Y, Z , has only two independent components, that shall be denoted as $\alpha_{\parallel} \equiv \alpha_X$ and $\alpha_{\perp} \equiv \alpha_Y = \alpha_Z$. Assuming for convenience x as the direction of the scattered field and z as the normal to the (x, y) scattering plane, the two most common experimental configurations are the VV and VH geometries. In both of them the incident field is vertically polarized, but while in the VV scheme the vertical component I_{VV} of the scattered intensity is measured, the orthogonal ("depolarized") I_{VH} component is detected in the VH scheme. I_{VV} and I_{VH} can be found by evaluating $\hat{\mathbf{n}}_z \cdot \boldsymbol{\alpha} \cdot \hat{\mathbf{n}}_z$ and $\hat{\mathbf{n}}_y \cdot \boldsymbol{\alpha} \cdot \hat{\mathbf{n}}_z$, after the particle polarizability tensor has been re-expressed in the laboratory fixed frame, in terms of the average particle polarizability $\bar{\alpha} = (\alpha_{\parallel} + 2\alpha_{\perp})/3$ and of the particle optical anisotropy $\beta = \alpha_{\parallel} - \alpha_{\perp}$.

Defining $\bar{n}_p^2 = \bar{\alpha}/V + 1$ and (provided that the optical anisotropy is small) $\Delta n = \beta/2\bar{n}V$, and assuming that $\bar{n}_p \approx n_s$, the final expression, after subtracting the solvent polarizability $\alpha_s = (n_s^2 - 1)V$, is

$$\begin{aligned} I_{VV} &= CV\bar{n}_p^2 \left[(\bar{n}_p - n_s)^2 + (4/45)(\Delta n)^2 \right] \\ I_{VH} &= CV\bar{n}_p^2 (\Delta n)^2 / 15. \end{aligned} \quad (29)$$

Note that I_{VV} can be written

$$I_{VV} = I_{coh} + 4/3 I_{VH} \quad (30)$$

where I_{coh} , which comes from the isotropic part of the polarizability tensor, depends only on the average refractive index of the particles.

Fig. 1 shows the experimental results for optically anisotropic particles in water (for an extensive discussion see Degiorgio et al., 1994). Since both I_{VH} and the second term at the r.h.s. of the expression for I_{VV} do not depend on n_s , a residual scattered intensity is present even in "best index matching" conditions $n_s = \bar{n}_p$. These contributions are the direct analogous, in depolarized RS, of the

Fig. 1 Experimental values for I_{VV} (●) and I_{VH} (○), normalized to their values for water suspensions, as a function of the solvent refractive index n_s for optically anisotropic colloidal spheres made of the partially-crystalline polymer perfluoro-alkylvinylether (PFA). The parabolic fit to I_{VV} yields an average particle refractive index $\bar{n}_p \simeq 1.36$ and an optical anisotropy $\Delta n \simeq 0.03$. As discussed in the text, I_{VH} does not depend on n_s . From Piazza R and Degiorgio V (2005) Scattering, Rayleigh. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl GL and Wyder P (ed.), vol. 5, pp. 234–242, Elsevier.

incoherent cross-section for neutron scattering. Notice that, although the depolarized scattering component cannot of course interfere with the orthogonally incident beam, the OT states that the sole *polarized* component still suffice to yield the *total* scattering cross section, including that due to depolarized scattering. The reason for this correct but apparently paradoxical result is discussed in Degiorgio et al. (2009).

Rayleigh-Gans-Debye (RGD) scattering. Most dispersed particles do not fulfill the strict requirements of the “pure” Rayleigh regime. A much more useful approximation can be obtained by letting the incident field vary, even appreciably, over the particle length scale, but requiring that the internal field does not appreciably differ from the incident one, both in amplitude and in phase. Weak amplitude changes simply imply $|n_p - n_s| \ll 1$, while tuning of the phases requires the optical path with or without the particles to be comparable, or

$$\frac{2\pi}{\lambda} |n_p - n_s| a \ll 1, \quad (31)$$

which, for $a > \lambda/2\pi$ is the more restrictive criterium framing the Rayleigh-Gans-Debye (RGD) regime. Notice that even particle with size $a \gg \lambda$ may satisfy (31), provided that there are sufficiently “faint”. Equating the internal and external fields amounts to neglecting effects on any given volume element δV of the fields scattered by the surrounding, so that the RGD regime is the equivalent of the First Born Approximation in quantum scattering. Each δV can therefore be considered as an independent elementary Rayleigh scatterer, and the total scattered field is obtained by summing overall volume elements, taking in due account the phase of each scattering contribution.⁶ Summing up overall volume elements, and allowing for nonuniformity of the particle refractive index by expressing $n_p = n_p(\mathbf{r})$, one obtains

$$\begin{bmatrix} s_1(\vartheta) \\ s_2(\vartheta) \end{bmatrix} = \frac{in_s k^3 V}{2\pi} F(q) \begin{bmatrix} 1 \\ \cos(\vartheta) \end{bmatrix}, \quad (32)$$

where

$$F(q) = \frac{1}{V} \int_V [n_p(\mathbf{r}) - n_s] \exp(i\mathbf{q} \cdot \mathbf{r}) d^3r. \quad (33)$$

By introducing the “characteristic function” $\chi(\mathbf{r}) = 1$ if $\mathbf{r} \in V$ and zero otherwise, $F(q)$ is seen to be the spatial Fourier transform of the distribution of the refractive index mismatch. For the special case of a particle with uniform refractive index distribution and vertical incident polarization, the scattered intensity is then given by

$$I(q) = I_0 \frac{V^2 k^4}{4\pi^2 R^2} (n_p - n_s)^2 P(q), \quad (34)$$

where

⁶Note that the phase shift of a wave scattered by an element placed at $\mathbf{r}$ compared to the contribution from a volume element centered around an arbitrary origin is $\Delta\varphi = \mathbf{k}_i \cdot \mathbf{r} - \mathbf{k}_s \cdot \mathbf{r} = \mathbf{q} \cdot \mathbf{r}$.

$$P(q) = \frac{1}{V^2} \left| \int_V \exp(i\mathbf{q} \cdot \mathbf{r}) d^3 r \right|^2, \quad (35)$$

called the particle *form factor*, is readily seen to represent an “intraparticle” structure factor. The scattering pattern in the RGD approximation can therefore be evaluated by a straight geometrical integration: for homogeneous spheres, for instance, $F(q)$ is simply proportional to the spherical Bessel function $J_{3/2}(qa)$, and analytical expression can be found also for ellipsoids, long rods, and thin disks. RDG scattering considerably extends the class of particles for which an easy analysis is feasible. A particularly interesting situation is colloidal fractal aggregation induced by the addition of salt. Fractal clusters grow with time, soon becoming much larger than λ , but they also became more and more “tenuous”. Therefore, their average refractive index becomes more and more matched with the solvent, and it can be shown that, asymptotically, RGD conditions are always fulfilled.

Finally, note that the expression for the scattering matrix in the Rayleigh-Gans-Debye approximation suffers from the same problem found in the pure Rayleigh (small particle) limit. To get a consistent expression for the extinction coefficient, the particle polarizability should again be modified according to Eq. (25).

Mie scattering. The exact solution for RS from an arbitrary sphere was obtained in 1908, with a real mathematical *tour de force*, by Mie (1908). Here only the main features of the results are described and some of their general traits commented. First, the general solution is fixed by only two parameters, namely $m = n_p/n_s$ and the dimensionless size $x = ka = 2\pi n_s a/\lambda$, and is formally given by

$$s_1 = -\sum_n \frac{2n+1}{n(n+1)} (a_n \pi_n + b_n \tau_n) s_2 = -\sum_n \frac{2n+1}{n(n+1)} (a_n \tau_n + b_n \pi_n), \quad (36)$$

where

$$\pi_n(\vartheta) = P_n^1(\cos \vartheta) / \sin \vartheta, \quad \tau_n(\vartheta) = dP_n^1(\cos \vartheta)/d\vartheta$$

give, in terms of the associate Lagrange functions $P_n^1(\cos \vartheta)$, the angular distribution of the scattered light. The amplitude coefficients a_n and b_n are complicated functions of m and x . What is important to point out, however, is that their leading behavior is $a_n \sim x^{2n+1}$, $b_n \sim x^{2n+3}$, so that, for small particles, taking into account only the first terms in the summation is sufficient. By increasing n , the functions π_n and τ_n display in a polar diagram an increasing number of lobes, changing in direction and sign with n . For large particles, therefore, the sum of many terms tends to cancel out scattering at most angles. The only exceptions are the lobes that are present for all n around $\vartheta = 0^\circ$ and $\vartheta = 180^\circ$, the latter however alternating in sign. As a result, large particle tend to scatter predominantly forward, with a residual back-scattering cone.⁷ For very large particles, the forward lobe has a width $\Delta\vartheta \sim \lambda/a$, witnessing the merging of Mie scattering with classical diffraction theory. Fig. 2 compares the full Mie and approximate RGD solutions for polystyrene latex spheres in water.

The coefficients a_n and b_n are finite for all real values of x . However, for strongly and absorbing particles, they often present complex poles with very small values of the imaginary part. These ‘quasi-resonances’ lead to strong enhancement of specific modes, and are responsible for the beautiful colors often observed in suspensions of metallic colloids (Bohren and Huffman, 1983).

By exploiting the OT, the total extinction cross-section can be obtained directly as a sum over the coefficients a_n , b_n :

Fig. 2 Normalized scattering intensity versus scattering angle ϑ for polystyrene spheres ($n_p = 1.59$) in water for $\lambda_0 = 633$ nm. For each value of the ratio a/λ , indicated close to the curves, the full and dotted line are, respectively, the numerical result from Mie theory and corresponding RGD analytical solution. From Piazza R and Degiorgio V (2005) Scattering, Rayleigh. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl GL and Wyder P (ed.), vol. 5, pp. 234–242, Elsevier.

⁷This is why, for instance, one gets dazzled by backlighted drops on a windshield. Ful colors often observed in suspensions of metallic colloids (Bohren and Huffman, 1983).

Fig. 3 Extinction factor $Q_{\text{ext}} = \sigma_{\text{ext}}/\pi a^2$ for polystyrene spheres in water as a function of x (varied by fixing $\lambda = 560$ nm and increasing a). The steep rise at small x corresponds to the RGD regime, $Q \sim x^4$, while the rich sub-structure at higher x , shown in the inset, derives from the large number of contributing Mie modes. “Blue moon” effects may take place in the regions where $dQ_{\text{ext}}/dx < 0$. From Piazza R and Degiorgio V (2005) Scattering, Rayleigh. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl GL and Wyder P (ed.), vol. 5, pp. 234–242, Elsevier.

$$\sigma_{\text{ext}} = \frac{2\pi}{k^2} \sum_n (2n+1) \text{Re}(a_n + b_n). \quad (37)$$

For small particles, σ_{ext} goes as λ^{-4} as in the RGD approximation, but by increasing x it tends to level off with substantial oscillations. In particular, for a specific (narrow) particles size-range, it may happen that in the visible region σ_{ext} increases with λ (see Fig. 3): this takes places for instance, when volcanic bursts eject in the atmosphere huge quantities of large particles, giving rise to the effect of blue sun or moon (as the name suggests, a rare event indeed).

The strong propensity to forward scattering for large particles also allows explaining a puzzling fact about extinction. As shown in Fig. 3, in the limit $x \rightarrow \infty$, Eq. (37) yields a value for σ_{ext} which is the *double* of the particle geometric cross-section $\sigma_g = \pi a^2$, namely the particle subtracts from the incident beam twice the expected power. This is not an artefact, but a real effect: what happens, however, is that half of the scattered power is concentrated in the forward lobe, so that it is collected by any finite-size detector as the eye. Such an intuitive geometrical optic concept as “shadow” is therefore based on subtle scattering effects.

A final consideration concerns transfer of momentum by radiation pressure, which is of primary importance both for optical levitation and for particle trapping by laser tweezers. For non-absorbing particles, it is easy to show that the radiation pressure is given by

$$p_{\text{rad}} = I_0 (\sigma_s/\sigma_g) (1 - \langle \cos \vartheta \rangle),$$

where $\langle \cos \vartheta \rangle$ is an average over the scattering pattern distribution. For $a \ll \lambda$ one has $\langle \cos \vartheta \rangle \simeq 0$, and the radiation pressure increases approximately as a^4 . However, for very large particles $\sigma_s/\sigma_g \rightarrow 2$ and $\langle \cos \vartheta \rightarrow 1 \rangle$, so that radiation pressure decreases. Depending on size and material composition of the particle, there is therefore an optimal λ for efficient momentum transfer.

The limit of geometrical optics. A brilliant results by van de Hulst (1968) yields a rigorous link between scattering and simple “ray optics”. Namely, in the limit $x \gg 1$, a term of order n in the Mie expansion is mapped into a ray passing at a distance $(n+1)\lambda/2\pi$ from the particle centre.⁸ The Mie coefficients can then be split into two equal part leading, respectively, to diffuse refraction-reflection effects and to the forward diffraction cone. Obviously, classic ray optics is found to be incorrect near caustics and focal point.

Interacting particles

Interparticle interactions may consistently change the amount of radiation scattered by a particle dispersion. As a rule of thumb, attractive forces increase, while repulsive interactions decrease, the intensity of the scattered light. This can easily be grasped by recalling that RG is proportional to the (osmotic) compressibility of a fluid mixture, a result that still approximately holds for dispersions of particles that are not too big compared to λ .

⁸The number of “distinguishable” rays must be finite: a single “ray”, to be meaningful must be straight over a length $\ell \geq \lambda$, so that, because of diffraction, it must have a minimum spot area of the order of λ^2 .

More precisely, for a dispersion of particles at small but finite number density ρ interacting via an isotropic potential $U(r)$, the intensity of $I_0(\rho)$ light scattered in the forward direction is proportional to

$$I_0(c) \propto \rho(1 + 2B_2\rho)^{-1}, \quad (38)$$

where

$$B_2 = -2\pi \int_0^\infty r^2 \left(1 - e^{-U(r)/k_B T}\right) dr, \quad (39)$$

is the 2nd order (virial) coefficient of the expansion of the suspension osmotic pressure in terms of ρ . The contrasting effect of attractive vs. repulsive interactions is then evident from the opposite sign of the Boltzmann factor in Eq. (39).

For a suspensions of rigid particles that are not small compared to the wavelength (so that the scattering displays a nonnegligible q -dependence), the effect of interparticle interactions at any wave vectors can be obtained by writing the structure factor, Eq. (7), as a product of an internal contribution, which coincides with the form factor $P(q)$ in Eq. (33), times a purely interparticle term $S(q)$ coming from pair interactions, so to write $I(q) = I_0 P(q) S(q)$. It is worth emphasizing that such a “splitting” of the structure factors works only for *rigid* particles, whose size or shape is not altered by interparticle interactions, a conditions that is for instance often violated in dispersions of surfactant self-aggregates.

It is finally useful to point out that, if decoupling between translations and rotations holds, interactions affect only the “coherent” part I_{coh} in Eq. (30) for the scattering from optically anisotropic particles. Therefore I_{VV} , being independent from both solvent refractive index and interparticle forces, is just a sensitive probe of the local particle concentration.

The complex refractive index for interacting particles

As discussed above, interactions consistently modify the scattering cross-section of a colloidal dispersion. For instance, the intensity scattered by a suspension of charged particles can decrease by *orders of magnitude* by exposing the suspension by ion-exchange resins. One may therefore wonder whether Eq. (27) can be modified to properly account for the effect of interactions on the optical extinction, and if interparticle forces may possibly leave their signature on the real part of refractive index too. As anticipated in section “The optical theorem (OT)”, this is in general an intractable problem. Nevertheless, Parola et al. (2014) have recently developed an *exact* treatment valid to second order in the particle polarizability for all values of particle concentration. A key result of this investigation is that the contribution from multiple scattering events, even when negligible at finite q , is conversely found to be crucial to figure out why the forward scattering amplitude, and therefore light extinction, depends on interparticle interactions.

For a suspension of homogeneous spherical particles at volume fraction ϕ , the model in Parola et al. (2014) yields the following general expression for the real part n of the refractive index and for the extinction coefficient γ

$$\begin{cases} n = 1 + 2\pi\phi\alpha_p + 2\pi\left(\frac{\pi}{3}\phi^2 + \text{Re}[\tilde{C}]\phi\right)\alpha_p^2 \\ \gamma = 4\pi k\phi \text{Im}[\tilde{C}]\alpha_p^2 \end{cases} \quad (40)$$

which contain the real and imaginary parts of a dimensionless correlation factor $\tilde{C}$ that depends in a rather complex way on an integral over q of the Fourier transform $g(q)$ of the pair distribution function. When interactions are negligible, Eq. (40) yields the Mie solution approximated to second order in polarizability. In the general case, the correlation contribution to the extinction coefficient depends only on those values of p that are smaller than the maximum wave vector $2k$, corresponding to a scattering angle $\theta = \pi$, while effects on the real part of the refractive index are appreciable only when the peak the structure factor $S(q)$ falls within the accessible range $q \leq 2k$. A striking example of the effect of interactions on the refractive index is shown in Fig. 4 for a dispersion of hard-sphere (HS) particles at volume fraction $\phi = 0.5$, which is approximately the maximum packing fraction for a HS fluid. In the absence of correlation effects, the suspension refractive index would simply given by $\langle n \rangle = \phi n_p + (1 - \phi)n_s = (n_s + n_p)/2$. Fig. 4 conversely shows that, in the region close to the peak of the structure factor $S(q)$ (evaluated at the maximum accessible scattering wave vector $q = 4\pi/\lambda$), the correlation contribution $\Delta n = n - \langle n \rangle$ is far from negligible. The plot also shows that for the values of λ/a indicated by the open dots, the refractive index increases with increasing λ , which is the hallmark of an “anomalous dispersion” region. Although no true absorption is present, the overall trend actually resembles the behavior of the refractive index of a Lorentz oscillator close to its natural resonance frequency, which suggests that, besides in resonant absorption, anomalous dispersion may occur in the presence of any process like scattering that leads to extinction of the incident field.

Fig. 4 Excess correlation contribution $\Delta n = n - \langle n \rangle$ versus the wavelength λ scaled to the particle radius a a suspension of hard-sphere (HS) particles at a volume fraction $\phi = 0.50$, according to the model in Parola et al. (2014). The full line is the structure factor of the HS fluid evaluated at the maximum experimentally detectable wave vector $q = 4\pi/\lambda$ while the open dots indicate the “anomalous dispersion” region.

Dynamic Rayleigh scattering

Rayleigh scattering from dispersed particles is not *exactly* elastic. Particles in suspensions undergo Brownian motion, so that the phase (and, for optically anisotropic particles, also the amplitude) of the scattered field in Eq. (2) depends on time. This leads to a spectral broadening $\Delta\omega$ due, in fact, to Doppler shift of the incident radiation by the moving scatterer. This shift is extremely small, typically $\Delta\omega/\omega \ll 10^{-9}$. Therefore, $\Delta\omega$ cannot be resolved even by sophisticated interferometric methods, since it is much smaller than the intrinsic spectral broadening on any source.

A brilliant solution is looking at *intensity* fluctuations measured by a quadratic detector (photodiode, photomultiplier, CCD). Quadratic detection introduced indeed a “replica” of the spectrum shifted to base band (as in homodyne radio systems) that can be easily extracted. Even more, this scheme does not require an incident light with strict temporal coherence (laser are actually used, but only because of their brilliance). This clever idea stands at the roots of intensity correlation spectroscopy (also called “Dynamic Light Scattering”, DLS) methods, allowing to measure particle size from the behavior of the intensity time correlation function $g(t) = \langle I(0)I(t) \rangle$. A comprehensive analysis of the technique can be found in Berne and Pecora (1976), while a detailed review of recent advances in DLS and of its application to colloidal systems in Glatter (2018). Furthermore, novel ingenious intensity correlation schemes such as Differential Dynamic Microscopy (Cerbino and Trappe, 2008) and Photon Correlation Imaging (Duri et al., 2009) manage to provide space-resolved intensity correlation data, thus blending the powers of scattering and imaging. A review of these and related methods can be found in Piazza (2014).

Conclusion

Rayleigh scattering has been seen to stem from fluctuations of the refractive index. In a simple fluid, the latter are mostly due to spontaneous density fluctuations, and reflect structural correlations in the fluid via their proportionality to the structure factor $S(q)$, the Fourier transform of the density autocorrelation function. In a fluid mixture, the role of density is taken up by concentration, which implies that, for dilute solutions, RS is proportional to the osmotic compressibility. Quantum effects on RS are relevant even for weakly degenerate gases: For instance, in a gas of independent fermions, the Pauli exclusion principle introduces effective repulsions between the particle leading to a strong reduction of the scattered intensity.

Particularly interesting for applications in fields ranging from atmospheric optics to photonics is RS from dispersions of particles in the colloidal size range. To describe particulate systems, it is useful to introduce a dimensionless scattering function, or more generally a scattering matrix $s_{ij}(\vartheta, \varphi)$, whose specific form is dictated by the particle geometry and symmetry. A fundamental link between the total extinction cross-section and the scattering matrix in the forward direction is provided by the Optical Theorem. When the particles are noninteracting and scatter so weakly that multiple scattering is negligible, the single particle scattering function directly yield through the OT both the real and the imaginary part of the refractive index.

The form of the scattering matrix depends on the particle size and shape and on the polarizability of the constituting material. Depending on these parameters, one can tell apart different scattering regimes, ranging from isotropic scattering for particles much smaller than the wavelength, to Rayleigh-Gans scattering for “optically tenuous” particles, where the scattering angular pattern is given by the particle form factor, to the exact, albeit involved, solution obtained by Mie for spheres of any size a and particle polarizability that merges in the limit $ka \gg 1$ with geometrical optics. The intensity scattered by particles made of an optically anisotropic material displays a depolarized component that, at variance with the usual component polarized as the incident field, does not depend on the refractive index of the solvent and is therefore present in index-matching conditions too.

The intensity scattered by a colloidal suspension is however highly influenced by the presence of interparticle interactions, which enhance or depress concentration fluctuations depending on whether they are, respectively, attractive or repulsive. Interaction effects can be accounted for by expressing structural effects as a product of an internal form factor times a purely interparticle term, but this is true only for particle whose size or shape is not affected by interactions. Notably, for optically anisotropic particles the depolarized component is not affected by the presence of interparticle forces. A recent analysis, exact to second order in particle polarizability, has shown that the contribution from multiple scattering is crucial in determining how the forward scattering amplitude, and therefore light extinction, depends on interparticle interactions.

Finally, consideration of the tiny frequency shift that is present even for RS led to development of Dynamic Light Scattering, and more recently of other techniques exploiting correlations of the scattered intensity, which have become powerful methods for particle sizing and, more generally, in the investigation of the Brownian dynamics of colloidal fluids and soft materials.

The de Haas–van Alphen (dHvA) and Shubnikov–de Haas (SdH) effects describe oscillatory components of the magnetization and conductivity, respectively, of a metal as a function of an applied magnetic field at low temperatures. The oscillations are periodic in a reciprocal magnetic field. It is the most accurate method to determine the contours of the Fermi surface of a metal or semimetal, but also gives information on other physical properties of electrons such as effective mass, scattering time, and spin-splitting factor.

Historical Introduction

The first experimental and theoretical manifestation of this effect dates back to 1930. In this year, L D Landau developed the quantum mechanical calculation of the diamagnetism of conduction electrons and mentioned the possibility of oscillatory effects there. But he believed, it was unobservable at that time. In the same year, L V Shubnikov and W J de Haas published an oscillatory behavior of the magnetoresistance in bismuth, and at the end of this year de Haas and P M van Alphen reported the observation of an oscillatory magnetization in the same material. Three years later, R Peierls developed a quantitative theory of the oscillations in Bi based on Landau's formulation of the energy levels of electrons in a magnetic field. In 1939, D Shoenberg determined the Fermi surface of Bi using the theoretical calculations of Landau. Shoenberg came to be the leading scientist in this field for several decades.

It was only around 1950 that general interest was seen in these oscillatory effects. In 1947, dHvA oscillations were detected in zinc, the first observation in a metal other than Bi. Soon after, it became clear that this effect could be observed in nearly every polyvalent metal, if crystals of high quality were available.

In the beginning of the 1950s, three important theoretical advances were made: first, the influence of the electron spin was worked out as a damping factor of the oscillation amplitude, second, R B Dingle could show that electron scattering broadens the Landau levels. This should change the oscillations in a way similar to a rise in temperature. The most important contribution was first published by L Onsager. He showed that the dHvA frequency is connected with the geometry of the Fermi surface and gives the extremal cross section of the Fermi surface perpendicular to the magnetic field. But this breakthrough could not be exploited immediately: at that time only low-frequency oscillations of the rather complex Fermi surfaces of polyvalent metals could be experimentally observed. On the other hand, band structure calculations were not yet good enough to show all details of a Fermi surface.

Around 1950, typical laboratory magnets produced fields up to 3 T. The very few water-cooled high-power magnets available at that time suffered from their instability. It was clear that higher and/or more stable magnetic fields are needed. Shoenberg, therefore, started working with pulsed fields up to 10 T and was soon able to observe high-frequency oscillations also in polyvalent metals, and even made the first observations in monovalent metals.

On the basis of prior theoretical work, I M Lifshitz and A M Kosevich developed a complete theory of the dHvA effect in 3D metals published in 1956. Together with improved band structure calculations starting from 1960, dHvA oscillations were investigated in all metals and compared with the theoretical band structure.

Although the basic investigations of the metallic elements are more or less completed, the dHvA and SdH effects are still of high use in the investigation of new compounds. Important examples are heavy fermion systems and low-dimensional conductors such as organic metals or artificially grown 2D electron systems.

Basic Theoretical Models

Landau Quantization

The physical reason for the oscillatory effects in a magnetic field can be easily understood in the model of a free electron gas confined to a cube of length L . (The electron spin is neglected first.) The Schrödinger equation for free electrons in a magnetic field is given by

$$\frac{1}{2m_e} \left(\frac{\hbar}{i} \nabla - e\mathbf{A} \right)^2 \Psi = E\Psi$$

where m_e is the electron mass, e is the electron charge, and $\mathbf{A}$ is the vector potential of the magnetic field $\mathbf{B}$. Landau showed in 1930, that for a magnetic field applied in the z -direction the energy is given by

$$E = \left(n + \frac{1}{2} \right) \hbar \omega_c + \frac{\hbar^2}{2m_e} k_z^2$$

with $n=0, 1, 2, \dots$, $\omega_c=eB/m_e$ being the cyclotron frequency and $k_z=2\pi n_z/L$ ($n_z=0, \pm 1, \pm 2, \dots$) the wave vector in the z -direction. If one compares this to the solution of a free electron gas without a magnetic field, where $E = \hbar^2 k^2/2m_e$, it is seen that the wave vector in the x, y -plane perpendicular to the magnetic field is no longer quasicontinuous, but takes only discrete values

$$k_{x,y} = \sqrt{(n + 1/2) 2m_e \omega_c / \hbar}$$

All permitted states lie on concentric tubes parallel to the magnetic field called Landau cylinders. The energy levels belonging to a certain n are highly degenerate. The degeneracy D is given by

$$D = \frac{eBL^2}{h}$$

This is the ratio between the magnetic flux BL^2 through the sample and the flux quantum h/e . The degeneracy is equal to the number of states contained in the adjacent interval of width $\hbar\omega_c$ of the electron spectrum in a zero field, that means, the adjacent states condense to the Landau tubes.

The cross-sectional areas of the Landau cylinders $S_k = \pi k_{x,y}^2$ are proportional to the applied magnetic field, that means, the Landau tube for a certain n increases as the field is increasing. In zero field, the electronic states are filled up to the Fermi level. In an increasing magnetic field, subsequent Landau levels pass through the Fermi energy and become depopulated (see Figure 1). This

Figure 1 Schematic drawing of a spherical Fermi surface with Landau cylinders.

gives an oscillatory dependence to the free energy of the electronic system and to all other quantities derived from it. From the linear dependence of S_k on B , it can be easily derived that the oscillatory component must be periodic in $1/B$ with the frequency F of the oscillations given by the extremal cross section S_{extr} of the Fermi surface, as was first pointed out by Onsager:

$$F = \frac{h}{e} S_{\text{extr}}$$

Lifshitz–Kosevich (LK) Formula

In 1956, Lifshitz and Kosevich published a theory of the magnetic susceptibility of conduction electrons in a metal with an arbitrary dispersion law. The oscillatory part of their solution turned out to be a complete description of the experimental results of the dHvA-oscillations measured in moderate magnetic fields and is still the standard to compare experiment with theory. They calculated the thermodynamic potential Ω of a gas of quasiparticles. The magnetization is then given by the thermodynamic relation:

$$M = -(\text{grad}_B \Omega)_{T,\mu}$$

The contributions to the oscillatory part come exclusively from the vicinity of the extremal orbits of the Fermi surface. For a certain extremal orbit, the oscillatory magnetization M parallel to the applied magnetic field is given by

$$M \propto \frac{F}{m} \left(\frac{B}{\partial^2 A_k / \partial k_z^2} \right)^{1/2} \propto \sum_{p=1} \frac{1}{p^{3/2}} R_T R_D R_S \times \sin \left[2\pi p \left(\frac{F}{B} - \gamma \right) \pm \frac{\pi}{4} \right]$$

F is the dHvA frequency, m is the cyclotron mass, $\partial^2 A_k / \partial k_z^2$ is the curvature of the cross-sectional area of the Fermi surface at the extremal orbit along the field direction, the factors R_T , R_D , and R_S are damping factors according to impurity scattering, temperature and spin, and γ is a value close to 0.5. The sign of the phase $\pi/4$ is dependent on the geometry: if the extremal orbit is a minimum, the sign is +; for a maximum, it is -. In normal situations, the cyclotron energy $\hbar\omega_c$ is much smaller than the Fermi energy and the oscillatory magnetization is dominated by the first harmonic in the summation over p .

In general, Fermi surfaces can be quite complicated and contain more than one extremal orbit. In that case, the total oscillatory component is a sum over all the contributions, each of which follows the LK formula, but with different parameters.

Without the reduction factors R_i the LK formula gives the idealized situation, where finite temperature, finite electron relaxation time, electron spin and other complications are neglected. At finite temperature, the occupation probability of a certain state with energy E is given by the Fermi Dirac function:

$$f(E) = \frac{1}{(1 + \exp((E - E_F)/kT))}$$

where k is the Boltzmann constant and E_F is the Fermi energy. This is a step function for $T=0$ K but is smeared out by kT around E_F at finite temperature. This smearing leads to a reduction of the dHvA amplitude by the temperature reduction factor R_T :

$$R_T = \frac{2\pi^2 p k m T / \hbar e B}{\sinh(2\pi^2 p m k T / \hbar e B)}$$

Typical dependencies of the reduction factor on the temperature at a magnetic field of 15 T are given in Figure 2 for several values of the normalized cyclotron mass m/m_e .

Real crystals are always imperfect in some respect. This leads to a finite relaxation time τ of electrons, which is equivalent to a broadening of the Landau levels. If this broadening is described by a Lorentzian distribution, the reduction of the oscillation amplitude is given by

$$R_D = \exp \left(\frac{-\pi p}{\omega_c \tau} \right)$$

This directly shows that the relaxation time must be long enough for the electron to complete a cyclotron orbit. The effect of impurities is similar to an increase in sample temperature. The reduction factor is generally given as

$$R_D = \exp \left(-\frac{2\pi^2 p m k T_D}{\hbar e B} \right)$$

with T_D being the so-called Dingle temperature, $T_D = \hbar / 2\pi k \tau$. The influence of T_D on the oscillation amplitude is shown in Figure 3 for free electrons ($m=m_e$). In samples with Dingle temperatures higher than a few kelvin, oscillations are hard to detect. Additional damping can be caused by sample and field inhomogeneities, mosaic spread, bending and strain on the sample, etc.

In a magnetic field, the spin degeneracy of the energy levels is lifted and each Landau level is split into two at energies $E \pm \frac{1}{2} \Delta E$ where

Figure 2 Temperature reduction factor of the fundamental frequency according to the Lifshitz–Kosevich theory at a magnetic field of 15 T for different values of the cyclotron mass.

Figure 3 Dingle reduction factor of the fundamental frequency according to the Lifshitz–Kosevich theory for different values of the Dingle temperature. The cyclotron mass is set equal to the free electron mass.

$$\Delta E = g\mu_B B$$

Here $\mu_B = e\hbar/2m_e$ is the Bohr magneton and g is the spin-splitting factor, which takes the value 2.0023 for free electrons. On increasing the field, the split Landau levels pass the Fermi surface at different field values. Therefore, a phase difference between these two oscillations arises and leads to a reduction of the amplitude by

$$R_s = \cos\left(\frac{1}{2}p\pi gm/m_e\right)$$

For free electrons the spin reduction factor is just $(-1)^p$, since the spin-splitting is equal to the Landau level spacing. In special cases, if $pgm/m_e = 1, 3, 5, \dots$, R_s becomes zero and the oscillation amplitude vanishes. This is called a spin-zero. The relation also shows that in the spin-zero of the fundamental frequency ($p=1$), the second harmonic becomes maximal.

Other Oscillatory Quantities

The standard method for the determination of Fermi surfaces of metals is the dHvA effect. But as mentioned above, the dHvA oscillations were derived from oscillations of the thermodynamic potential Ω . Therefore, it is clear that all other physical properties derived from Ω show an oscillatory behavior in a high magnetic field and there are many experimental investigations of these effects. Examples are the specific heat, magnetostriction, elastic properties, and the chemical potential. Oscillations of the chemical potential play an important role in quasi-two-dimensional (Q2D) systems as discussed later. In 3D systems, they are usually

weak and can be neglected in most cases. Another important quantity, which can be derived from the thermodynamic potential or calculated in a similar way, is the density of states at the Fermi energy.

There are oscillatory effects which cannot be described by thermodynamic relations alone since they involve nonequilibrium properties. The most famous example for it is the SdH effect, the oscillatory property of the magnetoresistance. As mentioned above, magneto-oscillations were first observed in the magnetoresistance of Bi in 1930. But it turned out that the SdH effect is very weak in normal metals and hard to detect there. In recent years the SdH effect has been of high importance, since it is easy to observe in Q2D electron systems such as quantum well structures or organic metals.
